Abstract

**Background:** To determine the effectiveness sustainability of the supervised balance training in the chronic ankle instability (CAI) cases with grade III ligament injury.

**Methods:** Twenty young adults (12 males and 8 females) diagnosed as CAI with grade III ligament injury underwent a 3-months supervised balance training. The self-reported functional questionnaire, plantar pressure, and isokinetic ankle strength were consecutively evaluated at pre-training, 3 months, 6 months and one year. Paired T test was used to explore the changes of muscle strength and foot pressure to evaluate the effectiveness sustainability of balance training. According to whether the patient has sprain recurrence, the patients were divided into sprain recurrence group and control group. The risk factors of sprain recurrence were explored with univariate analysis and multivariable logistic regression.

**Results:** The self-reported functional scores, the plantar pressure distribution and the muscle strength showed significant immediate improvements after 3-month supervised balance training. At post-training 6 months, peak force under 2nd metatarsal, time to peak force under the medial hindfoot, time to boundary measurements and dorsiflexion, and eversion strength were partly declined to the pre-training level. 16 patients (80%) resumed the daily life and sports without sprain recurrence during the follow-up. Four patients (20%) reported ankle sprain during the follow-up, and the sprain recurrence group showed significantly higher Beighton scores (p=0.012) and weaker initial inversion strength (p=0.022) than the control group.

**Conclusions:** Three months’ supervised balance training could effectively improve postural control and muscle strength of the CAI cases with grade III ankle ligament, although these improvements would be partial deceased over time. Additional strength exercises for dorsiflexion and eversion should be supplemented from 6 months. Higher Beighton score and initial inversion muscle strength weakness might increase the risk of sprain recurrence.

**Clinical registration:** ChiCTR1900023999, June 21th, 2019

**Introduction**

Lateral ankle sprain is a common musculoskeletal injury in sports\(^1\). Although most patients resumed daily life after the primary sprain, about 34% of individuals suffered from chronic ankle instability (CAI), which is characterized as recurrent sprain, episodes of giving-way of the ankle joint, pain, deficits of postural control and muscle strength\(^1\). Treatment strategy includes conservative or operative solutions, mainly depending on the severity of ankle sprains, which are classified from grades I to III (mild, moderate or severe)\(^2\). Conservative treatment is more effective for CAI patients with Grade I and Grade II ligament injuries while treatment for the chronic ankle instability (CAI) with grade III injuries is controversial \(^3\). Surgery is commonly recommended to CAI patients, especially to those with combined intra-articular lesions (osteocondral lesions (OCLs), osteophyte, impingement, loose body, etc) causing obstructive...
symptoms\textsuperscript{4–6}. However, considering the invasiveness and potential complications of the surgery, conservative treatment could be the first choice for the CAI cases with isolated lateral ankle ligament but without intra-articular lesions.

Balance-training programs were proven to be effective in improving postural control and muscle strength in CAI patients\textsuperscript{7} in short term. However, some research suggested that the effectiveness of conservative treatment (such as subjective symptoms\textsuperscript{8} and eversion muscle strength\textsuperscript{9}) might be temporary, and about 21.4\% CAI patients still had re-sprains\textsuperscript{8} and the postural stability deficits at 6 months post-intervention\textsuperscript{9}. However, previous studies merely targeted some single treatment (such as resistance tubing\textsuperscript{8} and wobble board\textsuperscript{9}), and the follow-up period was only 6 months. In addition, those studies included the CAI cases with varying degree of ligament injury but did not distinguish the CAI cases with grade III ligament injury. By now, there has been few evidences for long-term effectiveness and continuity after systematic rehabilitation training for CAI patients with grade III ligament injury.

In terms of the post-training functional evaluation, most of the studies focused on the subjective feeling instead of objective evaluation, thus, made it difficult to guide the clinical practice. In fact, the foot pressure measures, such as center-of pressure (COP) excursion, time-to-boundary (TTB) and peak plantar analysis have been commonly used to identify the postural control deficits of those with CAI. The CAI cases had significantly less time to make postural corrections to meet the stability demands\textsuperscript{10} and a significantly increased lateral loading\textsuperscript{11} compared with healthy controls. These objective parameters might be important predictors for the effectiveness sustainability and help treatment decision making.

In the present study, 20 CAI patients with isolated lateral ankle ligament injury were included and accepted 3-months supervised balance training and consecutive follow-up for 1 year. The purpose of present study was to determine the mid-term effectiveness and the sustainability of balance training program and preliminarily explore the risk factors of sprain recurrence in the CAI cases. We hypothesized that balance training would improve the muscle strength, foot pressure distribution and postural stability, but some improvements would be weakened with time. These results may help us optimize rehabilitation strategies to improve the effectiveness of balance training for the CAI cases with grade III ankle ligament injury.

**Materials And Methods**

**Design**

From Sep 2018 to Apr 2019, 20 CAI patients who were diagnosed as grade III ligament injury and ready for rehabilitation were included in the study. A priori power analysis was completed using data from a previous study in which the researchers examined the effects of a similar balance-training program\textsuperscript{12}. The study was approved by the IRB Medical Committee of our hospital (IRB00006761-M2019164) and the written content was obtained from all patients. The study was registered in Chinese Clinical Trial Registry (ChiCTR), and the number was ChiCTR1900023999.
Patient enrollment

The inclusion criteria were (i) aging from 18 to 40, (ii) a history of at least one significant lateral ankle sprain (at least 12 months prior to study enrolment) that caused inflammatory symptoms and disrupted activity, (iii) the most recent ankle sprain occurred >3 months prior to study participation, (iv) reports of the previously injured joint “giving way” and/or recurrent sprain and/or “feelings of instability” (v) scoring <24 on the Cumberland Ankle Instability Tool (CAIT)\textsuperscript{13}; grade III\textsuperscript{14-15} injury of anterior talofibular ligament (ATFL) and/or calcaneofibular ligament (CFL) confirmed by both MRI and positive anterior drawer test (increased translation of 3 mm compared to the uninjured side or an absolute value of 10 mm of displacement)\textsuperscript{16} and talar tilt test (10° of absolute talar tilt or 5° difference compared to the contralateral side)\textsuperscript{17} by TELOS SD 900 Stress Device (Austin & Associates, inc. USA). All patients presented without a history of neurological or orthopedic impairment. Patients with combined intra-articular lesions (OCLs, osteophyte, impingement, loose body, etc), a history of surgery, fracture requiring realignment and/or acute injury to the musculoskeletal structures (bone, joint structure and/or nerve) in either lower limb were excluded.

Upon enrollment, all the patients’ basic information was collected and evaluated, including the gender, age, height, weight, involved side, pre-duration, sprain time and the Beighton score. The Beighton score ≥ 4 was defined as the generalized joint hypermobility (gJHM). Then all the participants underwent the 3-month balance training intervention. The progressive balance-training program divided into 24 supervised training sessions, two sessions (60 minutes each session) per week. The postintervention data-collection session occurred within 48 hours after the intervention ended. A follow-up session was performed 3 months, 6 months and 1 year since the pre-intervention data-collection session. Participants were instructed to cease all interventions during the follow-up session. During each data-collection session, we administered the patient-oriented outcomes (Foot and Ankle Ability Measure (FAAM), Cumberland Ankle Instability Tool (CAIT)) before evaluating the disease-oriented outcomes (isometric ankle strength, foot pressure and static and dynamic postural control).

Table 1. Participants’ information
| Characteristics (n=20)   | Values           |
|------------------------|------------------|
| Age, y                 | 26.4 ± 5.2       |
| Height, cm             | 167.1± 8.4       |
| Weight, kg             | 60.3 ±9.5        |
| No. of sprains         | 8.2 ± 4.1        |
| Months since last sprain| 21.1 ± 21.6     |
| Sex, men: women        | 12: 8            |
| Beighton score         | 3.3 ± 2.3        |
| CAIT                   | 15.4±5.3         |
| FAAM ADL               | 67.6±10.3        |
| FAAM sport             | 55.9±11.4        |

FAAM, Foot and Ankle Ability Measure, CAIT, Cumberland Ankle Instability Tool.

**Plantar pressure and posture control evaluation**

The patients underwent three trials of single-limb stance on each leg with eyes closed on a force plate (AMTI; Watertown, MA, USA) for 10s\(^{10,18}\). COP data were calculated from the three-dimensional force and moment signals and sampled at a rate of 50 Hz.\(^{18}\) Subjects were instructed to stand as still as possible during testing with arms folded across their chests, holding the opposite limb at approximately 45° of knee flexion and 30° of hip flexion in accordance. If a subject touched down the ground, contacted with the stance limb, or was unable to maintain standing posture during the 10-s trial, the trial was terminated and repeated. TTB measures and COP measures were computed separately in the ML and the AP directions using previously described methods\(^{10,18}\).

Subjects walked six times in barefoot over the pressure plate (Footscan, RSscan International, Olen, Belgium) with 120 Hz sampling rate\(^{19}\). Three walks for each foot were recorded and printed. Each print consisted of a time peak-force curve for eight regions of interest on the foot. The regions of interest, which were analyzed automatically by the system software, were medial heel (HM), lateral heel (HL), 1st to 5th metatarsal heads(M1~M5), and toes(T1). The time variables were calculated as the ratio of time from the start of the stance to peak force under the region of interest and the total stance time. The peak force variables were calculated as the ratio of the peak force under the region of interest, and were normalized by the body weight\(^{20}\).

**Isokinetic strength measurement**
As described in TW Kaminski’s research\textsuperscript{21}, isokinetic strength was assessed with a Biodex isokinetic dynamometer (Biodex Medical Systems Inc, Shirley, NY). Each subject’s foot was securely fastened on the biodex chair, with the hip angle 80° flexion (0° neutral position) and 20° to 30° of knee flexion. Each subject was allowed three submaximal (50% capacity) warm-up repetitions at each velocity to become familiar with the isokinetic test procedure, then performed three maximal concentric test repetitions at 60 and 120°/s on both ankles. The resting interval was approximately one minute between tests for each motion, velocity, and side. At the end of testing, peak torque data were extracted from the torque curves.

**Balance training protocol**

As was shown in table 2, the balance training protocol was designed based on the widely used protocol from the published papers\textsuperscript{22-23}. The protocol includes single-legged stance, wobble board, resistant band and hop exercises and so on.

**Table 2.** The balance training protocol.
| Exercise               | Description                                                                 | Progression                                                                                                                                 |
|------------------------|-----------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------|
| Single-legged stance   | Performed up to 60s per repetition for up to 3 repetitions.                  | Progressed when participants could complete a 60-s trial without a loss of balance.                                                      |
|                        | Performed with eyes opened and eyes closed                                  | Increased no. of repetitions by 1                                                                                                       |
|                        |                                                                             | Changed surface from floor to using the Dyna-Disc.                                                                                       |
| Wobble board           | Slowly moved the board in the plantar-flexion/dorsiflexion and inversion/eversion directions without letting the board contact the floor. | Progressed when participant could complete the task without upper extremity support.                                                        |
|                        | Performed up to 10 repetitions in each direction.                           | Added rotational directions.                                                                                                            |
| Steamboats             | Tied a 48-in Thera-band around the unstable ankle.                         | Progressed when participants could complete the repetitions without a loss of balance or fatigue.                                         |
|                        | Positioned stance foot 27-in from where Thera-band was tied.                | Increased no. of repetitions from 10 to 15.                                                                                                |
|                        | Performed up to 3 sets of 15 repetitions in each direction (hip flexion, extension, abduction, adduction). | Progressed to next level of resistance with the Thera-band.                                                                            |
| Single-legged hop      | Hopped as far as comfortable in the anterior direction.                     | Progressed when participants could perform the task with minimal ankle and hip motion and no loss of balance on landing.                 |
|                        | Performed up to 15 repetitions.                                             | Increased no. of repetitions from 5 to 10 to 15.                                                                                          |
|                        |                                                                             | Encouraged increased distance to participants’ tolerance.                                                                               |
|                        |                                                                             | Progressed to medial, lateral, and posterior directions.                                                                               |
| Quadrant hop           | Hopped in numbered squares clockwise and counterclockwise while maintaining single-legged stance. | Progressed when participants could complete 2 sets of 5 hops without a loss of balance or fatigue.                                       |
|                        |                                                                             | Made unanticipated directional changes where investigator randomly called out numbers.                                                |
| Single-legged ball catch | Performed up to 3 sets of 20 tosses                                        | Progressed when participants could perform 20 tosses without a loss of balance.                                                         |
|                        |                                                                             | Tossed ball outside participants base of support.                                                                                         |
Performed during stance on a DynaDisc.

| Activity          | Description                                                                                                                                  | Progression                                                                                     |
|-------------------|--------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------|
| Toe touch down    | Maintained single-legged stance on a step while lowering the unstable ankle in the anterior, posterior, medial, and lateral directions until the foot contacted floor. | Progressed when participants could complete all trials without a loss of balance and with good lower extremity alignment (no eversion collapse) |
|                   | Performed up to 3 sets of 10 repetitions.                                                                                                        | Increased no. of repetitions from 5 to 10.                                                        |
|                   |                                                                                                                                                | Increased height of step from 4 in to 12 in in 2-in increments                                     |
| Hop ups and downs | Hop off step and landed in single-legged stance on floor.                                                                                      | Progressed when participants could complete all hops without a loss of balance or fatigue.      |
|                   | Performed up to 3 sets of 10 repetitions.                                                                                                      | Increased no. of repetitions from 5 to 10.                                                        |
|                   |                                                                                                                                                | Increased height of step from 4 in to 12 in in 2-in increments                                     |
|                   |                                                                                                                                                | Changed direction of hop.                                                                      |
|                   |                                                                                                                                                | Hopped up onto step.                                                                            |

Risk factors analysis

Based on the ankle sprain recurrence after the balance training program through one year, the patients were divided into the sprain recurrence group and control group. The pre-training variables for each patient was used to analyze the risk factor for the sprain recurrence after the balance training.

Data analysis

The self-reported function (FAAM and CAIT), postural control measures (TTB measures and COP-based measures, plantar pressure measures) were analyzed separately at pre-training, post-training, 6 months and 1 year. Paired sample t test was used to assess changes in the dependent measures before and after balance training. Shapiro-Wilk test was used to assess Normality of data. Univariate analysis and multivariable logistic regression model were used to explore the risk factors of sprain recurrence after the balance training, Alpha level was set a priori at \( p < 0.05 \). An a priori power analysis was completed using data from a previous study\(^2\) in which the researchers examined the effects of a similar balance-training program. Based on an \( \alpha \) level of .05, a power of 0.95, and an effect size of 0.97 determined by the FAAM-Sport, 16 participants were needed. Therefore, we enrolled 20 participants to account for up to 20% attrition.

Results
**Self-reported questionnaire**

The changes of self-reported function questionnaires are presented in the Figure 1. Compared with the pretraining values there was a significant increase for the FAAM ADL ($p<0.05$) and FAAM Sport ($p<0.05$) and CAIT ($p<0.05$) at follow-up. Numbers of recurrent sprains decreased from 3.29±2.87 to 1.63±2.02 at one-year follow-up. However, there was four patients (20%) still reported a sense of instability with at least once sprain recurrence while other 16 patients (80%) patients went back to pre-injury sport and general life.

**Plantar pressure distribution and postural stability**

During the walking, a significant increase in the peak force under the M2 (2.4±1.2 vs 3.2±1.9 N/kg, $T=3.79$, $p=0.011$) and HM (3.2±0.9 vs 4.0±1.2 N/kg, $T=3.99$, $p=0.034$) at 3 months follow-up, and the changes of peak force in HM (3.6±0.9 vs 5.0±1.7, $T=4.03$, $p=0.032$) lasted till 6 months (Figure 2. a, b). For the time to peak force (TPF), it showed significant decrease in M2 (79.5±8.5 vs 72.3±7.9%, $T=2.98$, $p=0.031$) and increase in HM (12.6±4.6 vs 19.1±4.9%, $T=-2.65$, $p=0.047$) only at 3 months follow-up. No other differences were found at 6 months follow-up compared with the pretraining value. The foot pressure distribution changes in three-dimension model of two individuals from respective control group and recurrence group were shown in the Figure 3.

During the single leg standing, TTB measurements were found significantly different with the pretraining level after 3-month training immediately (Figure 2. c, d). After 3 months’ balance training program, TTBAPa ($T=3.58$, $p=0.02$) and TTBMLa ($T=3.36$, $p=0.02$) temporarily increased and then decreased to the pretraining level while TTBAPm and TTBMLm showed continued improvement at follow up ($p<0.05$). There were no significant differences for the COP measures through all the time point ($p>0.05$).

**Muscle strength**

As was shown in Figure 4, all the isokinetic contraction strength was significantly improved after 3 months’ balance training ($p<0.05$). Continuously significant increase in the 120°/s, 60°/s PF and 120°/s IV strength was observed during the one year follow up ($p<0.05$), but the dorsiflexion and eversion muscle strength decreased to the pretraining level ($p>0.05$) after six months till one year and the improvements in the partial(60°/s) inversion muscle strength decreased after one year.

**Risk factors of sprain recurrence**

To preliminarily explore the potential risk factors of recurrence, the univariate analysis and multivariable logistic regression model were used. Based on whether the scores <24 CAIT or there was an obvious ankle sprain during the follow up, the patients were divided into the sprain recurrence group (n=4) and the control group (n=16). The baseline values in those two type individuals were analyzed with univariate analysis. Significant differences were found in the 60°/s inversion strength, Beighton scores, peak force under first metatarsal, medial hindfoot and lateral hindfoot (Appendix file 1, all $p<0.05$). Using univariate analysis results (Variables $p<0.1$) and forward selection to create a multivariable logistic regression
model, we found that the lower 60°/s isokinetic inversion muscle strength (OR, 1.46; 95% CI, 1.23-1.98; 
p=0.012) and a higher Beighton score (OR, 1.27; 95% CI, 1.03-1.32; p= 0.032) could be the risk factors. (Table 4)

Discussion

The most important finding of the present study was that the 3 months of supervised balance training 
significantly improved self-reported function, postural control, and muscle strength for CAI patients with 
isolated ligament injury. However, some improvements on postural control and muscle strength were 
declined after 6 months and 1 year. Additional strength exercises for dorsiflexion and eversion should be 
supplemented from 6 months. The generalized joint hypermobility (gJHM) and the initial inversion 
strength weakness could be the potential risk factors for sprain recurrence after balance training.

According to the results, most of CAI patients with grade III ligament injury had satisfactory outcomes 
after the balance training. Similar self-reported function questionnaire25-26 and muscle strength27-28 
improvements were also found in the previous studies, but none of them investigated the long-term 
effectiveness of balance training and distinguish the severity of the ligament injury. The results of the 
present study implicated that the balance training is still effective even for patients with severe ligament
injuries in the long run. Although the ligaments are completely broken in the acute phase and the joints are obviously loose in the chronic phase, the feeling of instability is partly improved by increasing the muscle strength and the posture control. However, we found that the strength improvement in dorsiflexion and eversion disappeared in the 6 months follow-up and a similar situation occurs with 60° eversion muscle strength at 1 year. It could be inferred that balance training will have a short-term muscle strength improvement and additional strength exercises for dorsiflexion and eversion from 6 months and inversion exercise from 1 year might enhance and maintain the effect of balance training again. Further studies are needed to improve the balance training program for the CAI cases.

For the plantar pressure evaluation, we found a significant change in the TTB related measures during the single leg standing. TTB related measurements was a spatiotemporal analysis of COP data points, which was a novel approach to assessing postural control deficit in single-limb stance\textsuperscript{10, 29}. It quantified the theoretical amount of time an individual had to use to make a postural correction to maintain postural stability. The results indicated that the grade III CAI patients needed longer time to reach the balance boundaries and less risk to fall after the balance training. During the walking, we found that the TPF of HM came more delayed and M2 came earlier after the balance training, which means a shorter duration of contact of the heel to central forefoot. The longer duration indicated a slowing down of weight transfer from heel strike to toe off, which was a sign of walking stability improvement\textsuperscript{20}. The results also showed that greater loading under the M2 and HM which indicates a medial shift of the center of pressure so as to decrease the susceptibility of ankle sprain\textsuperscript{11}. However, improvements on stability during single leg standing and pressure distribution during walking was declined gradually over time.

The present study showed that the sprain recurrence patients had significant higher Beighton scores, which indicated that the patients with gJHM might have poor rehabilitation effect for balance training. Some previous studies\textsuperscript{30-31} reported generalized joint hypermobility was an intrinsic risk factors related to recurrent lateral ankle sprain, so the hypermobility of ankle joint structure might increase the risk of ankle injury during the rehabilitation process. Similar poor outcomes were also found in the clinical surgery treatment, such as the modified Broström procedure\textsuperscript{16, 32}. In those cases, the repaired ligaments would eventually stretch out and the patients need a longer period for lateral ligament recovery. However, the impact of gJHM on conservative treatment effect was rarely reported. In theory, the increased muscle strength brought by functional training can enhance joint stability. However, the joint capsule of these patients with gJHM may be also with excessive relaxation, so that the improvement of muscle strength is not enough to restore sufficient stability. This may be the reason for the relatively poor results of these patients. Considering the limited number of cases, the effect and the mechanism of joint hyper-relaxation on conservative training requires further controlled studies.

In this study, we also found the relatively weaker 60°/s inversion strength could be another risk factor of the failure. Several studies have shown that subjects with CAI exhibited strength deficits in their invertor musculature\textsuperscript{33-35}. It is suggested that the ankle joint invertors play an integral role in controlling the rate of calcaneal eversion as the body’s center of mass is displaced laterally beyond the base of support\textsuperscript{36}. 

The present study showed that the sprain recurrence patients had significant higher Beighton scores, which indicated that the patients with gJHM might have poor rehabilitation effect for balance training. Some previous studies\textsuperscript{30-31} reported generalized joint hypermobility was an intrinsic risk factors related to recurrent lateral ankle sprain, so the hypermobility of ankle joint structure might increase the risk of ankle injury during the rehabilitation process. This may be the reason for the relatively poor results of these patients. Considering the limited number of cases, the effect and the mechanism of joint hyper-relaxation on conservative training requires further controlled studies.
The weakness in inversion strength lead in uncontrolled weight transfer to the lateral side of the foot during balance training, thus increased frequency of ankle inversion episodes. For the patients with inversion strength weakness, more specific and targeted rehabilitation needed to be done.

To our knowledge, this is the first comprehensive study to investigate the long-term effectiveness and its related factors of sprain occurrence for the CAI patients with isolated grades III ligament injury. The strength of this study included a relatively long-term follow-up, a detailed systematic balance training protocol and a comprehensive evaluation of the patients and the objective assessment on the postural control improvement in terms of plantar pressure and TTB. It was important to note that although some improvements seem not to last over time, the rehabilitation for the severe type of CAI patients were still effective in the long term. Our results provided more evidence for the use of balance training in CAI cases and would help to optimize the rehabilitation plan. Those with high-risk factors might be prompted to receive more aggressive treatment early, including surgery.

There were still some limitations of the present study. Firstly, the sample size was relatively small in the sprain recurrence group although overall participants enrolled in this study was calculated by the sample size, larger sample are needed to be included in the future research. Secondly, this study was included merely lateral ligament injury while other ligament and syndesmosis injuries also impeded rehabilitation outcomes. So, our results were only suitable for the isolated lateral ankle ligament injury, the balance training for more complex injury type are needed in the future.

**Conclusion**

For the grade III CAI patients with isolated lateral ankle ligament injury, the 3 months’ supervised balance training program significantly improved FAAM scores, foot pressure distribution, static postural control and muscle strength. However, the effectiveness may be partial declined after 6 months and 1 year. Additional strength exercises for dorsiflexion and eversion should be supplemented from 6 months. The high Beighton score and the initial inversion muscle strength weakness might be the potential risk factors of sprain recurrence after balance training.

**Figures**

**Figure 1**

Pre-training and post-training scores of the FAAM and CAIT. (a), (b) represents changes in the FAAM and CAIT respectively. * indicated p< 0.05 for comparisons within the pretraining and each time point of post-training.
Figure 2

Measurements during the walking (a, b) and the single limb standing (c, d) TTBML(AP)m: mean value of the minimum time to boundary in the medial-lateral (anterior-posterior) direction, TTBML(AP)a: absolute minimum time to boundary in the medial-lateral (anterior-posterior) direction. HM, Medial heel; M2, the 2nd metatarsal heads. Dotted line indicates the declining variables after the balance training. * indicated p<0.05 for comparisons within the pretraining and each time point of post-training.
Figure 3

Foot pressure distribution changes of the patient from respective control group (a~d) and sprain recurrence group (e~h) in three-dimension model (Screenshot from footscan 7.0 software). The figures showed the peak force during the walking at pretraining, 3, 6 and 12 months post training. After the balance training, the foot distribution in the control group turned to the medial side of foot (a~d) while the foot distribution in the sprain recurrence group turned to the medial side then reversed to lateral side of foot again (e~h).
Figure 4

Measurements of isokinetic contraction muscle strength. Dotted line indicates the declining muscle strength after the balance training. PF, plantarflexion; DF, dorsiflexion; EV, eversion; IV, inversion. * indicated p< 0.05 for comparisons within the pretraining and each time point of post-training.
