ABSTRACT
Prophylactic paracetamol administration impacts vaccine immune response; this study (www.clinicaltrials.gov: NCT01235949) is the first to assess PHID-CV immunogenicity following prophylactic ibuprofen administration. In this phase IV, multicenter, open-label, randomized, controlled, non-inferiority study in Romania (November 2010–December 2012), healthy infants were randomized 3:3:3:1:1:1 to prophylactically receive immediate, delayed or no ibuprofen (IIBU, DIBU, NIBU) or paracetamol (IPARA, DPARA, NPARA) after each of 3 primary doses (PHID-CV at age 3/4/5 months co-administered with DTPa-HBV-IPV/Hib at 3/5 and DTPa-IPV/Hib at 4 months) or booster dose (PHID-CV and DTPa-HBV-IPV/Hib; 12–15 months). Non-inferiority of immune response one month post-primary vaccination in terms of percentage of infants with anti-pneumococcal antibody concentrations ≥0.2 µg/mL (primary objective) was demonstrated if the upper limit (UL) was <10% for ≥7/10 serotypes. Immunogenicity and reactogenicity/safety were evaluated, including confirmatory analysis of difference in fever incidences post-primary vaccination in IIBU or DIBU group compared to NIBU. Of 850 infants randomized, 812 were included in the total vaccinated cohort. Non-inferiority was demonstrated for both comparisons (UL was <10% for 9/10 vaccine serotypes; exceptions: 6B [NIBU], 23F [IIBU]). However, fever incidence post-primary vaccination in the IIBU and DIBU groups did not indicate a statistically significant reduction. Prophylactic administration (immediate or delayed) of paracetamol decreased fever incidence but seemed to reduce immune response to PHID-CV, except when given only at booster. Twenty-seven serious adverse events were reported for 15 children; all resolved and were not vaccination-related.

Introduction
Pneumococcal conjugate vaccines (PCVs) provide protection against invasive pneumococcal disease (IPD) and other diseases such as acute otitis media or pneumonia;1-4 PCVs have been included in many national childhood immunization programs.

Co-administration of PCVs with standard infant vaccines was shown to induce a higher incidence of fever in children compared to single-vaccine administration.5-7 Antipyretics, most commonly paracetamol and ibuprofen, are sometimes administered prophylactically to prevent fever during pediatric immunization.8 Although prophylactic paracetamol administration significantly decreases febrile reactions, it has also been shown to reduce immune responses to some vaccine antigens.9 Prophylactic paracetamol administration (immediate and 6–8 hours post-
vaccination) with 10-valent pneumococcal non-typeable *Haemophilus influenzae* protein D conjugate vaccine (PHiD-CV) transiently lowered immune response after primary and booster vaccination. Induction of immunological memory and persistent impact of PHiD-CV on carriage rates were observed until at least 28 months post-booster vaccination.\(^{10}\) The observed trend toward lower antibody geometric mean concentrations (GMCs) prior to boosting may have significance for those children who might miss their booster dose, as their antibodies may decline faster than if they had not received paracetamol. Prophylactic administration of paracetamol also seemed to interfere with immune responses to the PCV13 in infants, while ibuprofen appeared to reduce responses to pertussis filamentous haemagglutinin (FHA) and tetanus antigens without impacting pneumococcal responses.\(^{11}\)

In contrast to these data, a recent study showed that prophylactic administration of paracetamol in children after concomitant vaccination with a multicomponent meningococcal serogroup B vaccine (4CMenB), DTPa-HBV-IPV/Hib and PCV7 decreased fever and reactogenicity, with no apparent clinically relevant effect on immune responses.\(^{12}\)

To date, there are no published data concerning the impact of prophylactic ibuprofen administration on the immune response to PHiD-CV.\(^ {13}\) This study aimed to demonstrate non-inferiority of the immune response to PHiD-CV administered as a 3-dose primary course with immediate (IIBU) or delayed (DIBU) versus no prophylactic ibuprofen (NIBU) administration, in terms of percentage of infants with anti-pneumococcal antibody concentrations ≥0.2 μg/mL. Non-inferiority was to be demonstrated if, for ≥7/10 serotypes, the upper limit (UL) of the 98.25% confidence interval (CI) of the difference between groups (NIBU vs IIBU and NIBU vs DIBU) was <10%, in compliance with the European Medicines Agency Guideline on the Choice of the Non-inferiority Margin.\(^ {14}\) Additionally, the study aimed to demonstrate a lower incidence of febrile reactions with immediate or delayed ibuprofen administration vs no ibuprofen administration.

We also assessed the effect of paracetamol administration (immediate or delayed, the latter not yet studied) on the immunogenicity and reactogenicity of PHiD-CV and the co-administered routine infant vaccines after primary and booster vaccinations. With this information, clinicians can objectively assess if the benefits of prophylaxis of febrile reactions outweigh the risk of potential effects on immunization.

### Results

#### Study participants

The study was conducted between 12 November 2010 and 08 December 2012. Of 850 participants randomized, 812 were included in the total vaccination cohort (TVC) for primary vaccination and 768 in the TVC for booster vaccination (Fig. 1); 647 (79.7%) children from the primary and 575 (74.9%) children from the booster epoch were included in the according-to-protocol (ATP) cohort for immunogenicity. Demographic characteristics were similar between groups (Table S1). The mean age at primary vaccination was 13.1 (standard deviation: 1.18) weeks at first dose, 18.0 (1.48) weeks at second dose, and 23.1 (1.78) weeks at third dose; the mean age at booster vaccination was 12.3 (0.62) months. There were no major differences between groups in the total daily dose of administered antipyretics. Two children in the TVC were withdrawn due to a serious adverse event (SAE) during the study period; these SAEs were not considered to be causally related to vaccination.

#### Effect of ibuprofen on PHiD-CV immunogenicity

One month post-primary vaccination, for each of the 10 vaccine serotypes, the percentage of children in the IBU groups with antibody concentrations ≥0.2 μg/mL was at least 98.7%, except for serotypes 6B and 23F (6B at least 84.0%; 23F at least 89.2% in each group). Non-inferiority in terms of the percentage of infants with antibody concentrations ≥0.2 μg/mL was demonstrated since the UL of the difference was <10% for 9 out of 10 serotypes for each comparison (IIBU vs NIBU and DIBU vs NIBU). The UL was >10% for serotypes 6B (IIBU vs NIBU: percentage difference 0.69; UL = 10.99%) and 23F (DIBU vs NIBU: percentage difference 2.73; UL = 11.04%). No statistically significant differences in antibody GMCs for vaccine pneumococcal serotypes or protein D were observed (Table 1).

Post-booster immune responses were in similar ranges in all groups; for each of the vaccine serotypes, percentages of children with antibody concentrations ≥0.2 μg/mL were 91.5–100%. An increase in antibody GMCs post-booster compared to post-primary vaccination was observed in all groups, for each vaccine serotype except serotype 14 in the DIBU-NIBU group and serotype 19F in the NPARA-IPARA group (Table S2). Because very few participants per group had available results from the opsonophagocytic activity and poliomyelitis neutralization assays, these results could not be presented and interpreted.

For vaccine-related serotypes 6A and 19A, antibody concentrations ≥0.2 μg/mL were observed for ≥43.3% and ≥40.1% of children in each IBU group at one month post-primary vaccination (Table 1), and for ≥80.4% and ≥78.0% children post-booster, respectively (Table S2).

#### Effect of paracetamol on PHiD-CV immunogenicity

Post-primary vaccination, the percentage of children with antibody concentrations ≥0.2 μg/mL generally tended to be lower in the immediate (IPARA) and delayed paracetamol (DPARA) groups than in the no-paracetamol (NPARA) group (however, the 95% CI of the differences included 0) and the highest difference in point estimates vs control NPARA was observed for serotype 6B (~8% for IPARA and ~14% for DPARA). Compared to the NPARA group, antibody GMCs were lower for 6 of the PHiD-CV serotypes and protein D in the IPARA group, and for serotypes 1 and 6B in the DPARA group (Table 2).

One month post-booster vaccination, for each of the 10 vaccine serotypes, at least 91.7%, 93.2% and 97.9% of children in the IPARA-NPARA, DPARA-IPARA and NPARA-IPARA groups, respectively, had antibody concentrations ≥0.2 μg/mL. Post-booster antibody GMCs tended to be lower than in the control NIBU-NIBU group for all vaccine serotypes in the IPARA-NPARA group and the majority of serotypes in the DPARA-IPARA group, as well as for protein D in both...
groups. No major differences in antibody GMCs were observed when paracetamol was administered only during booster vaccination (NPARA-IPARA group) (Table S3).

For vaccine-related serotypes 6A and 19A, antibody concentrations/C21mg/mL were observed for C2130.0% and C2141.5% of children in each PARA group at one month post-primary vaccination (Table 2), and for C2183.0% and C2177.3% children post-booster (Table S3).

Effect of ibuprofen on co-administered antigens
Post-primary vaccination, a borderline significant difference in antibody GMCs was observed in the IIBU vs NIBU comparison for FHA (UL D0.99), in the DIBU vs NIBU comparison for tetanus (UL D1.00) and in the IIBU vs NIBU comparison for hepatitis B surface antigen (HBs) (UL D1.01) (Table 3). Post-booster, a difference in pertussis antibody GMCs was observed in the IIBU-DIBU (anti-pertussis toxoid [PT], anti-pertactin [PRN] and anti-FHA antibody GMCs) and IIBU-NIBU (anti-PT antibody GMCs) groups (Table S4). Seroprotection and seropositivity rates were not affected.

Effect of paracetamol on co-administered antigens
Concerning the co-administered vaccine antigens for which the results were interpretable (diphtheria, tetanus, pertussis [PT, FHA, and PRN], HBs and Haemophilus influenzae type b polysaccharide phosphate [PRP]), antibody GMCs seemed to be reduced in the IPARA and DPARA groups and in the NPARA-IPARA group for some antigens; nevertheless, seroprotection/seropositivity rates remained high (C2195.5%) (Table 3, Table S5). In detail, the antibody GMCs tended to be lower for post-primary anti-PRP (ratio of 0.66) and anti-tetanus (ratio of 0.78) in the IPARA group and for post-primary anti-tetanus (0.81) in the DPARA group (Table 3), as well as for post-booster anti-PT in the NPARA-IPARA and IPARA-NPARA groups compared to the control group (Table S5).

Factorial design analysis
Comparison of antibody GMCs in the 9 booster groups that received ibuprofen did not indicate a combined effect (interaction) of prophylactic antipyretic regimen at primary and booster vaccination, and no individual effect of ibuprofen at primary vaccination or at booster on the PHiD-CV post-booster immune response.

Safety results
The confirmatory analysis of the difference in fever incidences in the IIBU or DIBU groups compared to NIBU did not demonstrate any statistically significant reduction. Fever during primary vaccination was reported for 122 children (61.3%) in the NIBU group, compared to 121 (61.4%) in the IIBU group (difference: ¡0.11% [97.5% CI: ¡11.04; 10.82]) and 101 (51.3%) in the DIBU group (difference: 10.04% [97.5% CI: ¡1.15; 20.98]). Grade 3 fever was reported only in the NPARA and DIBU-DIBU group (Fig. 2). Similar results were obtained in the complementary descriptive analysis on the ATP cohort: fever incidence in the NIBU...
The study found no clinically relevant impact of immediate or delayed prophylactic administration of ibuprofen during primary or booster vaccination on the immune response to PhID-CV. A factorial design analysis indicated neither a combined effect (interaction), nor separate effects of prophylactic ibuprofen administration at primary and booster vaccination on the post-booster immune response to PhID-CV.

For the primary objective, a threshold of 0.2 μg/mL antipneumococcal antibody concentrations was used (equivalent to 0.35 μg/mL measured by the non-22F ELISA of the WHO.
Table 2. Exploratory analysis: serotype-specific pneumococcal and protein D antibody responses with pairwise group comparisons for the paracetamol groups, one month post-dose three (ATP cohort for immunogenicity).

| Reference laboratory. For most vaccine serotypes, almost all children in each study group (≥96.3%) reached this antibody concentration at 1 month post-primary vaccination, except for serotypes 6B (≥72.5%) and 23F (≥81.1%).

Prophylactic administration of paracetamol during primary series showed a trend for reduced post-primary anti-pneumococcal antibody GMCs when given immediately after vaccine administration (for the majority of vaccine serotypes) or when given in a delayed manner (for some serotypes). The proportion of children with post-primary antibody concentrations ≥0.2 μg/mL was not impacted except for serotypes 6B and 23F, thus the clinical relevance remains unknown. Observations related to immediate administration of paracetamol are in line with previous findings.9

When paracetamol was given immediately only at the booster dose, corresponding to the age with highest risk of febrile seizures,15 we observed no effect on immune response to PHID-CV while fever was reduced. This suggests that paracetamol can be used for prophylaxis of febrile reactions at booster dose. In contrast, the post-booster immune response to PHID-CV appeared to be impacted when paracetamol was administered either immediately at primary vaccination but not post-booster, or in a delayed manner at primary vaccination and immediately at booster dose.

Descriptive comparisons of the response to co-administered antigens showed a trend for lower anti-FHA post-primary antibody GMCs in the ibuprofen groups except for pertussis antigens (PT, FHA, and PRN in the IIBU-DIBU group, and PT in the IIBU-NIBU group vs the NIBU-NIBU group). However, seroprotection and seropositivity rates for the co-administered antigens one month after primary vaccination and immediately at booster dose.

The exclusion of 1 from the 95% CI of antibody GMC ratios was used to highlight potential group differences (bold).
vaccination and one month after booster dose were not affected by ibuprofen prophylactic administration, suggesting no clinically relevant impact.

Our findings differ from in vitro assessments, in which ibuprofen was found to have a dose-dependent effect on antibody production in human peripheral blood mononuclear cells and in purified B cells, with the major influence on antibody production observed when ibuprofen was administered early (day 2 and 3) to the culture.16

Immediate or delayed prophylactic administration of paracetamol during primary vaccination did not reveal major differences in seroprotection and seropositivity rates or in antibody GMCs of co-administered antigens. When no antipyretics were given at booster dose, a trend for decreased post-booster antibody GMCs was observed for the majority of co-administered vaccine antigens, with no impact on seroprotection and seropositivity rates, indicating no or limited clinical relevance.

A previous study assessing the effect of prophylactic immediate administration of paracetamol at the time of vaccination with PHID-CV and DTPa-HBV-IPV/Hib found generally lower antibody GMCs for antibodies against diphtheria, tetanus, PRN and PRP antigens after primary vaccination.9 After booster vaccination, this tendency was only observed for antibodies against tetanus. Moreover, this study showed that the seropositivity or seroprotection rates were not impacted and remained in line with previous experiences with DTPa-based or pneumococcal vaccines with the exception of serotype 6B after primary vaccination.9

Our results correspond with findings recently reported for PCV13, in which immediate prophylactic paracetamol administration seemed to interfere with infant series immune response to PCV13, while immediate prophylactic administration of ibuprofen did not interfere with pneumococcal responses but may reduce responses to pertussis FHA and tetanus antigens. These effects were especially apparent when antipyretic prophylaxis was administered at the time of primary vaccination, while no differences were observed after the booster dose.11

In contrast, another recent study did not show any apparent clinically relevant impact on immune responses to 4CMenB and to the concomitantly administered routine vaccines (DTPa-HBV-IPV/Hib and PCV7) when paracetamol was administered prophylactically to prevent post-immunization fever in children.12 The different outcomes might be related to differences in the study design, including vaccination schedule, age of children at the time of vaccination, route of administration of the antipyretic, and different vaccines used for immunization.
The diverging effects of prophylactic paracetamol and ibuprofen administration on vaccine immunogenicity could be explained by differences in the antipyretics mode of action and pharmacokinetics in infants and children.\(^\text{17}\) Ibuprofen non-selectively inhibits both cyclooxygenase (COX)-1 and COX-2, while paracetamol is thought to selectively block COX-3 in brain and spinal cord,\(^\text{18}\) although this latter mechanism of action has been disputed.\(^\text{19}\) While ibuprofen and other non-steroidal anti-inflammatory drugs inhibit cyclooxygenase through competing with arachidonic acid for the active site of the enzyme, paracetamol acts by reducing ferryl protoporphyrin IX at the peroxidase site of the cyclooxygenase enzyme.\(^\text{18}\) Furthermore, it was hypothesized that non-steroidal anti-inflammatory drugs lead to lower levels of produced antibodies due to a decreased expression of B lymphocyte-induced maturation protein 1, which in turn leads to less terminal differentiation of proliferating B-cells into plasma cells.\(^\text{20}\) Unlike ibuprofen, paracetamol inhibits myeloperoxidase-catalyzed oxidant production and, by decreasing hypochlorite production at the inflammation site, could impair immunogenicity by decreasing antigen processing and cross-priming.\(^\text{21}\) Both ibuprofen and paracetamol can rapidly cross the blood-brain barrier, and the latter may act in a synergistic manner on the opioidergic and serotonergic systems.\(^\text{22,23}\)

The specific impact of paracetamol on vaccine response could also be explained by the generation of an active metabolite which inhibits the uptake of anandamide and increases its concentration in the brain and blood.\(^\text{24,25}\) Anandamide is a ligand which inhibits the uptake of anandamide and increases its bioavailability.\(^\text{24}\) This mechanism of action could also be explained by the generation of an active metabolite.\(^\text{25}\) While ibuprofen and other non-steroidal anti-inflammatory drugs inhibit cyclooxygenase through competing with arachidonic acid for the active site of the enzyme, paracetamol acts by reducing ferryl protoporphyrin IX at the peroxidase site of the cyclooxygenase enzyme.\(^\text{18}\) Furthermore, it was hypothesized that non-steroidal anti-inflammatory drugs lead to lower levels of produced antibodies due to a decreased expression of B lymphocyte-induced maturation protein 1, which in turn leads to less terminal differentiation of proliferating B-cells into plasma cells.\(^\text{20}\) Unlike ibuprofen, paracetamol inhibits myeloperoxidase-catalyzed oxidant production and, by decreasing hypochlorite production at the inflammation site, could impair immunogenicity by decreasing antigen processing and cross-priming.\(^\text{21}\) Both ibuprofen and paracetamol can rapidly cross the blood-brain barrier, and the latter may act in a synergistic manner on the opioidergic and serotonergic systems.\(^\text{22,23}\)

The study had several strengths: the factorial design addressed all possible combinations of ibuprofen use, a parallel assessment of paracetamol in the same study was performed, and good compliance with the complex study procedures was observed. A limitation of the current study is that very few results were available from the opsonophagocytic activity and poliomyelitis neutralization assay due to insufficient sera volumes; thus, these results could not be interpreted. In addition, no adjustment for multiplicity was performed for the exploratory group comparisons so the results based on these analyses should be interpreted with caution.

Because prophylactic administration of paracetamol at primary vaccination tends to impact post-primary and post-booster antibody GMCs while ibuprofen was shown not to affect immunogenicity, ibuprofen could be considered as the antipyretic of choice for prophylaxis during primary vaccination courses. However, ibuprofen prophylaxis appeared to have no or only limited effect on fever rates. Thus, prophylactic use of ibuprofen and its benefit/risk ratio should be cautiously considered when deciding in choice of prophylactic antipyretic.

Paracetamol may be more suitable for prevention of febrile reactions after booster vaccination in the second year of life, as it appeared to have no detrimental effect on immunogenicity when administered at booster dose only. However, its use around primary vaccination and benefit/risk ratio should be assessed individually.

Finally, a more conservative approach would be to not provide prophylaxis at all, except when the individual patient would require it. Results of our study may help in guiding general practitioners, pediatricians, and policy makers in their recommendation and choice of antipyretics for prophylaxis of post-vaccination febrile reactions in children.

**Methodology**

**Study design and participants**

In this phase IV, multicenter, open-label, randomized, controlled study performed in Romania, infants aged 12–16 weeks...
at the time of first vaccination (Fig. 3), born after a gestation period of 36–42 weeks and without any obvious health problems, were enrolled. Written informed consent was obtained from each participant’s parents or legally authorized representatives. Exclusion criteria are presented in the supplementary material.

The study was conducted according to Good Clinical Practice, the Declaration of Helsinki, and the local rules and regulations of the country; when deviations from these guidelines and regulations were detected, corrective actions were implemented where needed, including exclusion of participants from analyses. This was the case for one study site, at which all study-related activities were terminated during the study due to lack of confidence in the integrity of the data. The infants enrolled at this site were withdrawn from the study, offered continuation of vaccination outside the study and excluded from analyses. As these participants were equally distributed over the different groups, this exclusion had no major impact on the interpretation of the data. The study was registered at www.clinicaltrials.gov (NCT01235949). A protocol summary is available at www.gsk-clinicalstudyregister.com (study ID: 112921).

Randomization and masking

Enrolled infants were randomized using a blocking scheme (3:3:3:1:1:1) into 3 ibuprofen (IBU) groups and 3 paracetamol (PARA) groups, to receive after each dose of primary vaccinations immediate, delayed, or no ibuprofen or paracetamol prophylactic administration. At booster vaccination, each IBU group (immediate, delayed, or no ibuprofen at priming) was further randomized (1:1:1) into 3 groups (immediate, delayed, or no ibuprofen at booster), while for the 3 PARA groups, treatment (immediate, delayed, or no paracetamol at priming) was re-allocated as defined in the protocol (Fig. 3). The randomization lists were generated at GSK using MATEX for SAS to number the study vaccines and the antipyretic doses given at primary and booster vaccination. Treatment allocation at the site was performed using GSK’s internet randomization system (SBIR): the site investigator accessed the randomization system on the internet and provided the identification number for eligible infants. The randomization system then used a minimization algorithm to determine the treatment number for the study vaccines and antipyretic doses to be used for the infant.

The study was conducted in an open manner; the participants’ parent(s) or legally acceptable representative, the investigator, and all study staff involved in the clinical evaluation of participants were aware of treatment allocation.

Procedures

Participants received 3-dose primary vaccination with PHiD-CV (Synflorix™, GSK, Belgium) at 3, 4, and 5 months of age and booster dose at 12–15 months of age (intramuscular, in the right thigh, or deltoid for children >12 months); 2 doses of DTPa-HBV-IPV/Hib (Infanrix hexa™, GSK, Belgium) at 3 and 5 months of age and booster dose at 12–15 months of age (intramuscular, left thigh or deltoid); and one dose of DTPa-IPV/Hib (Infanrix-IPV/Hib™, GSK, Belgium) at 4 months of age (intramuscular, left thigh). The first dose of antipyretic (ibuprofen (Nurofen™, Reckitt Benckiser, UK) – 10 mg/kg/dose, with a maximum daily dose of 30 mg/kg, or paracetamol (Panadol Baby™, GSK, UK) – 15 mg/kg/dose with a maximum daily dose of 60 mg/kg) was administered orally either immediately after vaccination at the study site (immediate administration) or by the parents at home 4–6 hours after vaccination (delayed administration). The second and third dose of antipyretic were administered by the parents at home, 6–8 hours after the previous dose; if a child slept overnight, the dose was deferred to the following morning.

Outcomes

The primary study outcome was to assess the percentage of infants with anti-pneumococcal antibody concentrations \( \geq 0.2 \mu g/mL \) for each of the 10 PHID-CV serotypes, in order to demonstrate non-inferiority of immune response to PHID-CV administered as a 3-dose primary vaccination course with immediate or delayed prophylactic ibuprofen compared to PHID-CV without prophylactic ibuprofen administration.

Secondary outcomes included determination of the percentage reduction in fever episodes with immediate or delayed prophylactic ibuprofen administration after primary PHID-CV vaccination (confirmatory objective). The percentage of participants with local and general adverse events within 4 days, with unsolicited AEs within 31 d after each vaccine dose, and the occurrence of SAEs during the entire study were also assessed. Another secondary outcome was the evaluation of the immune responses to the components of PHID-CV and the co-administered DTPa-HBV-IPV/Hib and DTPa-IPV/Hib vaccines, in terms of antibody concentrations one month post-primary immunization, prior to and one month after booster immunization.

Statistical analysis

Immunogenicity analysis

Immunogenicity analyses were performed for the primary and booster ATP immunogenicity cohort, comprising all evaluable participants (meeting all eligibility criteria and no elimination criteria, who complied with protocol-defined procedures/intervals) with results available for primary or booster immunogenicity endpoint measures.

Confirmatory inferential analysis for the primary objective

The global type I error for each pair-wise comparison was adjusted to 1.25% using a Bonferroni adjustment to ensure that the overall type I error was below 2.5%, considering that the 2 IBU groups were compared to the control group (without ibuprofen). The non-inferiority to the control group was further adjusted to account for endpoint multiplicity using the method by Lehman et al.\(^34\) leading to a nominal type I error = 1.25%\(^7/10\) = 0.875%. The statistical decrease in GMC was also adjusted to account for the 11 endpoints (10 serotypes and anti-protein D) using a Bonferroni adjustment, leading to a nominal type I error = 1.25%/11 = 0.11364%.

The study had no less than 92.1% power to detect a statistical difference for a true GMC decrease equal to 2-fold. To
obtain a power of 92.7% using an adjusted one-sided $\alpha$ of 0.875%, a sample size of 180 participants for each primary IBU group was necessary. Anticipating that $\geq 14\%$ of vaccinated participants would not be evaluable for the ATP cohort for immunogenicity, we planned to enroll 210 participants in each ibuprofen group.

Standardized asymptotic 98.25% CIs were computed using StatXact for the difference between groups in the percentage of participants with anti-pneumococcal antibody concentrations $\geq 0.2 \mu g/mL$ one month post-dose 3 (NIBU minus IIBU, or NIBU minus DIBU). Non-inferiority was demonstrated for one of the 2 pair-wise group comparisons if the UL of the 2-sided 98.25% CI was below 10% for at least 7 of the 10 vaccine pneumococcal serotypes.

99.8% CIs for antibody GMC ratios (IIBU/NIBU and DIBU/NIBU), one month post-dose 3, were computed for each of the 10 vaccine pneumococcal serotypes and protein D using a one-sided ANOVA test on the logarithm10 transformation of the concentrations. A statistically significant difference in post-dose 3 antibody GMCs was established if the UL of the 2-sided 99.8% CI was $< 1$ for at least one of the 10 vaccine pneumococcal serotypes or protein D.
Factorial analysis

The nine randomized booster IBU groups were designed to enable a factorial analysis in which 2 factors (factor A – ibuprofen administration at primary vaccination, factor B – ibuprofen administration at booster vaccination), and 3 levels for each factor (immediate, delayed or no ibuprofen administration), could be evaluated. Further details are provided in supplementary methods.

Exploratory analyses

The exploratory analyses for the IBU and PARA groups are detailed in the supplementary methods. Briefly, the exclusion of 0 from the 95% CI of difference between groups in percentage of participants with rectal temperature ≥38°C within 4 d after at least one primary dose (NIBU minus IIBU, or NIBU minus DIBU) were computed using StatXact. This secondary exploratory objective was assessable if the primary objective was reached, and was demonstrated if the lower limit (LL) of the 97.5% CI around the difference was higher than 0%.

Disclosure of potential conflicts of interest

OFP, MLN, GC, GB, SCM, CP, ACC, AEN, MB, ILB, CNS, VS, and VVL were investigators in the study and their institute (or in case of a private practice; themselves) received fees from the GSK group of companies for all study activities. In addition, SCM received fees from the GSK group of companies for attending GSK advisory boards and medical conferences. SCM was a research contractor for MSD and Boehringer Ingelheim. OFP was a research contractor for Sanofi, Pierre Fabre, Pfizer, Inventive Health, and a grant investigator for ESPID. GC was a board member, employee and grant investigator for "Profilaxia" Center and a grant investigator for Parexel. NF and DB are employed by the GSK group of companies. DB owns shares of the GSK group of companies. KS works as a consultant in XPE Pharma & Science for the GSK group of companies and is now employee and owns shares of the GSK group of companies.

Acknowledgments

The authors thank the children and their parents/legally acceptable representatives who participated in this study, the study nurses, and the GSK study team members (Katrien Clinckx, Lode Schuerman, Juan Pablo Yarzabal, Mireille Venken, Sadheer Ravula, and Kelly Iliev). The authors thank Patricia Lommel for statistical input at the time of protocol development. Authors also would wish to thank Judd-Hajnal Filip, Joke Vandewalle (XPE Pharma & Science), Kristel Vercauteren, Domenica Majorino and Bram Blomme (XPE Pharma & Science for GSK) for providing medical writing services and editorial support in preparing this manuscript. Finally, authors would wish to thank Hanne Callewaert and Caroline Hervé (GSK) for their input during draft development. The data of this study have been partially presented at the 33rd Annual meeting of the European Society for Pediatric Infectious Diseases (ESPID), Leipzig, Germany, May 12-16, 2015.

Synflorix, Infanrix-IPV/Hib, and Panadol Baby are trademarks of the GSK group of companies. Nurofen is a trademark of Reckitt Benckiser.

Funding

GlaxoSmithKline Biologicals SA was the funding source and was involved in all stages of the study conduct and analysis. GlaxoSmithKline Biologicals SA also funded all costs associated with the development and the publishing of the present manuscript. The corresponding author had full access to the data and was responsible for submission of the publication.

Contributors

DB, NF, KS, and MN designed the study. OFP, SCM, MN, AN, CP, GB, LB, MB, ACC, GC, VVL, and CS acquired the data. DB, NF, and KS analyzed the data. OFP, SCM, MN, AN, CP, GB, LB, MB, ACC, GC, VVL, CS and VS contributed to the conduct of the study (recruitment and monitoring of study participants). All authors participated in the interpretation of the data and all reviewed and approved the final version of the report.
