Abstract

Based on the short-time dynamic scaling form, a novel dynamic approach is proposed to tackle numerically the Kosterlitz-Thouless phase transition. Taking the two-dimensional XY model as an example, the exponential divergence of the spatial correlation length, the transition temperature $T_{KT}$ and all critical exponents are computed. Compared with Monte Carlo simulations in equilibrium, we obtain data at temperatures nearer to $T_{KT}$.

The Kosterlitz-Thouless (KT) phase transition is an important kind of phase transitions in nature [1,2]. When the temperature approaches the transition temperature $T_{KT}$ from above, the spatial correlation length diverges exponentially, rather than by a power law in a second order phase transition. Below $T_{KT}$, the system remains critical in the sense that the spatial correlation length is divergent. No real long range order emerges in the whole temperature regime. Important examples of systems with a KT transition are the classical XY-type models, quantum Heisenberg models, hard disk models and other relevant fluid systems as well as field theories.

It is well known that due to the exponential divergence at the transition temperature, numerical simulations of critical systems with a KT transition suffer severely from critical slowing down. For example, to compute the spatial correlation length of the two-dimensional classical XY model, even with the cluster algorithm and the over-relaxed algorithm one has only reached the temperature $T = 0.98$, which is still fairly far from $T_{KT}$ estimated to be around 0.89 to 0.90 [3–5]. If some quenched randomness is added to the system, e.g. in the fully frustrated XY model, the situation becomes even more complicated [6–10].

Recently much progress has been made in critical dynamics. It is discovered that universal dynamic scaling behavior emerges already in the macroscopic short-time regime, after a microscopic time scale $t_{mic}$ [11–19]. More interesting and important is that the static exponents originally defined in equilibrium enter the short-time dynamic scaling. This provides a possible way for extracting these exponents from the short-time dynamic scaling behavior [19]. Since the measurements are carried out in the macroscopic short-time regime, the method is free of critical slowing down.

Such a short-time dynamic approach has been systematically investigated for critical dynamic systems with a second order phase transition. It has been first verified in the simple Ising and Potts model [20,21] and recently applied successfully to general and complex systems as non-equilibrium dynamic systems [22–24], the chiral degree of freedom in the fully frustrated XY model [24] and lattice gauge theory [25]. The critical exponents as well as the critical temperature can be extracted either from the power law behavior of the observables at the early times or from the finite size scaling. Compared with the non-local cluster algorithms, the dynamic approach does study the dynamic properties of the original local dynamics.

However, it is not clear whether the short-time dynamic approach can systematically go beyond critical systems with a second order phase transition, even though first step approach or attempt has been made to the KT transitions and the spin glass transitions [26–29]. For systems with a KT transition, for example, owing to the absence of symmetry breaking and to the fact that the system remains critical below $T_{KT}$, a clear signal as for a second order phase transition does not exists for the transition temperature $T_{KT}$. The exponent $\nu$ and $T_{KT}$ have not been determined. Standard techniques developed for the second order phase transitions do not apply here. On the other hand, besides the exponents, whether one can obtain other critical properties of the equilibrium state as especially the spatial correlation length from the short-time dynamics remains unknown, even for second order phase transitions.

In this communication we propose a short-time dynamic approach to the KT transition taking the two-dimensional XY model as an example. From the short-time dynamic scaling, we extract the spatial correlation length of the equilibrium state. From the spatial correlation
length we estimate the transition temperature $T_{KT}$ and the static exponent $\nu$. With $T_{KT}$ at hand, the static exponent $\eta$ and dynamic exponent $z$ are obtained from power law behavior of the magnetization and Binder cumulant. There are no principle reasons to choose the XY model but only because there exist the most data of Monte Carlo simulations in equilibrium for comparison.

The XY model in two dimensions is defined by the Hamiltonian

$$ H = \frac{1}{T} \sum_{<ij>} \vec{S}_i \cdot \vec{S}_j , $$

(1)

where $\vec{S}_i = (S_{i,x}, S_{i,y})$ is a planar unit vector at site $i$ and the sum is over the nearest neighbors. In our notation, the coupling constant is already absorbed in the temperature. Large scale Monte Carlo simulations in equilibrium have been performed to understand the properties of the phase transition \[3–5\]. The spatial correlation length $\xi$ and susceptibility $\chi$ have been calculated in a temperature interval \([0.98, 1.43]\) with lattice sizes up to 512. The results support a KT singularity for the spatial correlation length $\xi(\tau) \sim \exp^{(b \tau^{-\nu})}$ (2)

and for the susceptibility $\chi(\tau) \sim \xi^{2-\eta}(\tau)$, with $\tau \sim (T - T_{KT})/T_{KT}$ being the reduced temperature. However, unconstrained four-parameter fits to the data do not yield completely satisfactory results \[3\]. The measured values of $\nu$ and $T_{KT}$ from the data of $\xi$ and $\chi$ are not very consistent and stable. $\eta$ estimated from $\chi(\tau) \sim \xi^{2-\eta}(\tau)$ is above 0.7 and too big compared with the theoretical prediction $\eta = 0.25$. The temperatures for the available data of $\xi$ and $\chi$ are still far from the transition temperature $T_{KT}$ estimated to be around 0.89 to 0.90 (for details, see Table 1 and Ref. \[3\]). However, simulations in equilibrium with lower temperatures are very difficult.

We will demonstrate that from the short-time dynamic scaling, the spatial correlation length $\xi(\tau)$ of the equilibrium state can be extracted with relatively small lattices. This is because the non-equilibrium spatial length $\xi(t, \tau)$ is small in the short-time regime of the dynamic evolution. Therefore, simulations can be performed at lower temperatures.

In this paper we consider only the dynamics of model A, which is relaxational without energy and magnetization conservation. Starting from an ordered initial state, e.g. all $\vec{S}_i = (S_{i,x}, S_{i,y}) = (1, 0)$, the system is updated at the temperature above $T_{KT}$ with the standard Metropolis algorithm. We stop updating at a certain Monte Carlo time $t_m$ and repeat the procedure. Total samples for average is from 800 to 1 200 for lattice size $L = 256$ and above 400 for $L = 512$. The lattice size $L = 256$ is used in simulations for temperatures from $T = 1.07$ down to 0.975, while $L = 512$ from $T = 0.97$ to 0.94. Extra simulations with other lattice sizes confirm that our data have no visible finite size effect.

The observable we measure is the magnetization defined as

$$ M(t) = \frac{1}{L^d} \sum_i < S_{i,x}(t) > . $$

(3)

From a general physical view point of the renormalization group transformation, the magnetization $M(t)$ is subject to a scaling form

$$ M(t, \xi(\tau)) = t^{-\eta/2z} M(1, t^{-1/z} \xi(\tau)). $$

(4)
When the temperature is at $T_{KT}$ (or below), i.e. $\tau = 0$, $\xi(\tau) \to \infty$ and $M(t)$ undergoes a power law decay $M(t) \sim t^{-\eta/2z}$. However, for $\tau > 0$, the power law behavior is modified by the scaling function $M(1, t^{-1/z} \xi(\tau))$. This fact can be used for the determination $\xi^z(\tau)$ and the exponent $\eta/z$.

In Fig. 1, the time evolution of the magnetization is displayed in log-log scale for different temperatures. We perform Monte Carlo simulations up to a time $t_m$ where there is visible deviation from the power law behavior. Actually, in the short-time regime of the dynamic evolution, the magnetization itself is more or less self-averaged. We may increase the lattice size without too much extra fluctuation. What restricts our simulations to very low temperatures is only $t_m$. Our longest updating time is $t_m = 50,000$ at the temperature $T = 0.94$. To obtain the curve for $T = 0.98$ one needs 8 days in ALPHAstation 500 (400MHz), while ten times more for $T = 0.94$.

Now from a scaling collapse of two curves with a pair of temperatures $(T_1, T_2)$, we estimate the ratio $\xi_1/\xi_2$ and $\eta/z$. Here $\xi_1$ and $\xi_2$ are the values of $\xi(\tau)$ at the temperatures $T_1$ and $T_2$ respectively. In Fig. 2 such a scaling plot is displayed for $(T_1, T_2) = (0.955, 0.965)$. We multiply the magnetization $M(t_1, \xi_1)$ by an overall factor $b^\alpha$ and rescale $t_1$ to $t_1/b$. According to the scaling form (1) this rescaled $M(t_1, \xi_1)$ is equal to $M(t_2, \xi_2)$ if and only if $b = \xi_1^z/\xi_2^z$ and $\alpha = \eta/2z$. Therefore, searching for the best fit between $M(t_2, \xi_2)$ and the rescaled $M(t_1, \xi_1)$ we determine $\xi_1^z/\xi_2^z$ and $\eta/2z$. In the figure, the circles represents the rescaled $M(t_1, \xi_1)$ best fitted to $M(t_2, \xi_2)$.

Theoretically the exponents $\eta$ and $z$ are defined at the transition temperature $T_{KT}$. The exponent $\nu$ and the exponential singularity in Eq. (2) are defined for temperatures above but in the close neighborhood of $T_{KT}$. If the temperature is fairly above $T_{KT}$, in principle, all the exponents and the parameters $b$ may have some dependence on the temperature. Usually this dependence on the temperature is neglected, otherwise the situation becomes too complicated. In our dynamic approach, we perform the scaling collapse of the magnetization with two temperatures which are not too far away each other and therefore the dependence of $\eta/z$ on the temperature are actually considered. However, we assume $\nu$ and $bz$ be independent of the temperature.

In Table I the measured ratio of $\xi_1^z/\xi_2^z$ and exponent $\eta/2z$ for different pairs of temperatures $(T_1, T_2)$ are listed. Errors are estimated by dividing the total samples for the time-dependent magnetization into two groups only. The lowest temperature we reach is $T = 0.94$. For comparison, in Table I available values of $\xi_1^z/\xi_2^z$ from Ref. 3 (denoted by †) are also given. They are slightly smaller than our results. We observe that as the temperature decreases, these values of $\xi_1^z/\xi_2^z$ do not increase sufficiently smoothly. Real errors of these data (and also our data) might be somehow bigger than given in the table. Taking $z = 1.96$ in Table I as input, the resulting $\eta$ from $\eta/2z$ in Table I is around 0.26 to 0.31. As expected, we see a tendency that $\eta$ will become around 0.25 as the temperature approaches $T_{KT}$.

Now we fit the data in Table II to the exponential form in Eq. (3) and estimate the transition temperature $T_{KT}$, the exponent $\nu$ and parameter $bz$. The best results are given in Table II in comparison with the those from simulations in equilibrium. Our results are fitted from a relatively lower temperature interval [0.94, 1.07], and agree well with those obtained in a temperature interval [0.98, 1.43] in Ref. 3, in both cases of an unconstrained fit and a fit with a fixed $\nu = 0.5$. However, as pointed out by the authors of Refs. 3,4, for the
unconstrained fit the minimum in the parameter space is not very stable in the directions of \( \nu \) and \( b_2 \). It is somehow by chance that our value of \( \nu = 0.48 \) is so close to \( \nu = 0.47 \) obtained in Ref. [5]. When we vary \( T_2 \) in the fitting interval \([0.94, T_2]\) from 1.07 to smaller values, the exponent \( \nu \) first drops down and then rises again after around \( T_2 = 1.00 \). These fluctuations very probably come from the fact that we do not have sufficient data points and accuracy for each data point. The estimate of \( T_{KT} \) is relatively stable. But the impression is that the value of \( T_{KT} \) might be slightly bigger than \( T_{KT} = 0.8942 \) given in the table, if the fitting can confidently be performed at the really close neighborhood of \( T_{KT} \).

With the transition temperature \( T_{KT} \) at hand, we proceed to measure the magnetization \( M \) and its second moment \( M^{(2)} \) at \( T_{KT} \). To seek for the dynamic exponent \( z \), we construct a Binder cumulant \( U = M^{(2)}/M^2 - 1 \). Finite size scaling analysis leads to the short-time behavior \[ U(t) \sim t^{d/z}. \]

Finally an accurate value of \( \eta/2z \) can be obtained from the power law decay of the magnetization \( M(t) \sim t^{-\eta/2z} \) (see Eq. (3)). In Fig. 3, \( M(t) \) and \( U(t) \) have been plotted in log-log scale. Since our measurements only extend to \( t = 750 \), a lattice size \( L = 64 \) is sufficient. Total samples for average is 12 000. From the slopes of the curves in the figure we measure \( d/z \) and \( \eta/2z \), then calculate \( z \) and \( \eta \). The results are included in Table I. Our \( \eta = 0.238(4) \) coincides with the best estimate \( \eta = 0.235(5) \) in equilibrium.

In conclusions, a dynamic approach is proposed to tackle numerically the Kosterlitz-Thouless phase transition. We demonstrate for the first time that not only the critical exponents but also the spatial correlation length of the equilibrium state can be obtained from the short-time dynamics. Taking the two-dimensional XY model as an example, the exponential divergence of the spatial correlation length is extracted from the short-time dynamic scaling. The transition temperature \( T_{KT} \), the static exponents \( \nu \) and \( \eta \) as well as the dynamic exponent \( z \) are then estimated. Since the measurements are carried out in the short-time regime of the dynamic evolution, where the non-equilibrium spatial correlation length is small, we do not encounter difficulties of generating independent configurations. Compared with the simulations in equilibrium, we can perform simulations at the temperatures closer to \( T_{KT} \). This method can in principle be applied or generalized to other kinds of phase transitions as second order phase transitions and spin glass transitions.
