Modeling Tissue and Blood Gas Kinetics in Coastal and Offshore Common Bottlenose Dolphins, *Tursiops truncatus*

Andreas Fahlman, Frants H. Jensen, Peter L. Tyack and Randall S. Wells

Bottlenose dolphins (*Tursiops truncatus*) are highly versatile breath-holding predators that have adapted to a wide range of foraging niches from rivers and coastal ecosystems to deep-water oceanic habitats. Considerable research has been done to understand how bottlenose dolphins manage O\(_2\) during diving, but little information exists on other gases or how pressure affects gas exchange. Here we used a dynamic multi-compartment gas exchange model to estimate blood and tissue O\(_2\), CO\(_2\), and N\(_2\) from high-resolution dive records of two different common bottlenose dolphin ecotypes inhabiting shallow (Sarasota Bay) and deep (Bermuda) habitats. The objective was to compare potential physiological strategies used by the two populations to manage shallow and deep diving life styles. We informed the model using species-specific parameters for blood hematocrit, resting metabolic rate, and lung compliance. The model suggested that the known O\(_2\) stores were sufficient for Sarasota Bay dolphins to remain within the calculated aerobic dive limit (cADL), but insufficient for Bermuda dolphins that regularly exceeded their cADL. By adjusting the model to reflect the body composition of deep diving Bermuda dolphins, with elevated muscle mass, muscle myoglobin concentration and blood volume, the cADL increased beyond the longest dive duration, thus reflecting the necessary physiological and morphological changes to maintain their deep-diving life-style. The results indicate that cardiac output had to remain elevated during surface intervals for both ecotypes, and suggests that cardiac output has to remain elevated during shallow dives in-between deep dives to allow sufficient restoration of O\(_2\) stores for Bermuda dolphins. Our integrated modeling approach contradicts predictions from simple models, emphasizing the complex nature of physiological interactions between circulation, lung compression, and gas exchange.

INTRODUCTION

The physiological adaptations that optimize foraging in marine mammals have long interested researchers. Optimal foraging theory implies that marine mammals should change dive behavior and metabolic pathways, and the fraction of aerobic and anaerobic metabolism based on dive depth and prey availability (Carbone and Houston, 1996; Cornick and Horning, 2003). Considerable work has been dedicated to understanding the aerobic limitations of diving air-breathing vertebrates, as these help with understanding foraging limits and efficiency. Kooyman et al. (1983) described the maximum dive duration until increasing blood lactate levels as the aerobic dive limit (ADL). The calculated ADL (cADL) was later defined as the total O_2 stores divided by the rate of O_2 consumption (Butler and Jones, 1997), and has been estimated in a number of species (Kooyman and Ponganis, 1998; Butler, 2006). However, metabolic rate may change over the course of a dive or foraging bout, and a few studies have subsequently estimated the cADL from measured (respirometry: Castellini et al., 1992; Reed et al., 1994, 2000; Hurley and Costa, 2001; Sparling and Fedak, 2004; Fahlman et al., 2008a, 2013) or estimated diving metabolic rate (doubly labeled water, or a proxy of metabolic rate: Boyd et al., 1995; Froget et al., 2001; Butler et al., 2004; Fahlman et al., 2008b).

Most studies agree that the majority of dive durations are well within the ADL/cADL, as this increases foraging efficiency and reduces lengthy surface intervals required to remove accumulated anaerobic by-products such as lactate (Kooyman et al., 1983). However, some species of otariids that feed on the benthos appear to exceed their cADL regularly, while those that feed in shallower water have shorter dive durations and seldom exceed the cADL (Costa et al., 2001). These differences may indicate true variation in foraging behavior, but may also be suggestive of morphological or physiological differences within or between closely related species that alter cADL (Hückstädt et al., 2016). For example, the muscle mass in previous studies was assumed to be similar to that of the Weddell seal (Costa et al., 2001), and such assumptions are often necessary as available data do not exist for all variables and species. However, variation in underwater swimming behavior (Williams, 2001; Fahlman et al., 2013), or morphological variation in muscle mass and fiber type (Pabst et al., 2016) may significantly alter the metabolic cost of foraging.

Large variations in dive behavior also exist within species. In the common bottlenose dolphin (Tursiops truncatus), different ecotypes have evolved to occupy different ecological niches (Mead and Potter, 1995; Hoelzel et al., 1998). Coastal bottlenose dolphins inhabit coastal areas and generally perform short (<60 s), shallow (<10 m) dives (Mate et al., 1995), while offshore bottlenose dolphins inhabit offshore, deep-water habitats and regularly dive below 200 m (Klatsky et al., 2007). Interestingly, neither resting metabolic rate nor lung compliance differed between the two ecotypes (Fahlman et al., 2018a,b), but blood hematocrit was significantly higher in the offshore ecotype (Klatsky et al., 2007; Schwacke et al., 2009; Fahlman et al., 2018a). In addition, the offshore ecotype is generally larger (Klatsky et al., 2007), possibly due to larger muscle mass to help increase the available O_2 stores and diving capacity. In an attempt to better understand the physiological limitations of these two ecotypes, and to explore how variation in morphology and anatomy may alter gas dynamics during diving, we used a previously published gas exchange model (Fahlman et al., 2009; Hooker et al., 2009; Hodanbosi et al., 2016) to estimate blood and tissue gas tensions for O_2 (PO_2), CO_2 (PCO_2), and N_2 (PN_2) from high resolution (1 Hz) dive records from coastal bottlenose dolphins sampled near the island of Bermuda.

MATERIALS AND METHODS

Model

The model described in this paper uses the breath-hold diving gas dynamics model developed by Fahlman et al. (2009) and Fahlman et al. (2006), which has been used to estimate lung, blood, and tissue gas tensions in a number of species (Hooker et al., 2009; Kvadsheim et al., 2012; Hodanbosi et al., 2016). A brief summary of the model is included below, with the specific changes made for the current modeling effort. The model was parameterized for bottlenose dolphins and was based on published values available for this species when possible, and otherwise on published values for beaked whales or phocids (as detailed below).

As in previous work, the body was partitioned into 4 compartments: brain (B), fat (F), muscle (M), and central circulation (CC), and one blood compartment (BL, arterial and mixed venous). In the current study, bone was included in the fat compartment as the bones of deep diving whales are high in fat content (Higgs et al., 2010). The central circulatory compartment included heart, kidney, and liver. The muscle compartment included muscle, skin, connective tissue, and all other tissues (Fahlman et al., 2009). In previous studies, the alimentary tract was placed in the central circulation. However, due to its lower metabolic rate, it was placed in the muscle compartment in the current study. The size of each compartment as well as the myoglobin and hemoglobin concentrations were initially taken from data on coastal dolphins (Mallette et al., 2016). As there is little or no information about the body composition of offshore dolphins, changes were made to the body composition of the offshore ecotype to be more like a beaked whale (Pabst et al., 2016).

Lung Gas Stores and Gas Exchange

Gas exchange occurred between the lungs and blood compartment and between the blood compartment and each other compartment (Fahlman et al., 2006). The O_2, CO_2, and N_2 stores in the lung consisted only of a gas phase and were assumed to be homogenous. We assumed that there was no diffusion resistance at the lung-surface interface when an animal was breathing at the water surface (Farhi, 1967). Thus, arterial blood tension of N_2 (Pa_N2), O_2 (Pa_O2), and CO_2 (Pa_CO2) were assumed to be equal to the alveolar partial pressures. For an animal breathing at the surface, we assumed that alveolar partial pressures of N_2 (Pa_N2), O_2 (Pa_O2), and CO_2 (Pa_CO2) were,
respectively, 0.74 ATA, 0.133 ATA, and 0.065 ATA (Fahlman et al., 2015), with 0.062 ATA being water vapor.

During diving, hydrostatic pressure compresses the respiratory system, which causes a pressure-dependent pulmonary shunt to develop (Fahlman et al., 2009). The parameters that describe the structural properties for the alveolar space and conducting airways (Equations 4 and 5 in Bostrom et al., 2008) were updated based on previously published compliance values for the bottlenose dolphin (Table 1, Fahlman et al., 2011, 2015; Moore et al., 2014).

Total lung capacity (TLC) included the volume of the dead space (trachea and bronchi, \( V_D \)), and the maximum alveolar volume (\( V_A \)), i.e., \( TLC = V_D + V_A \). It was assumed that gas exchange only occurred in the alveoli and when the diving alveolar volume (\( DV_A V_A^{-1} \)) was equal to 0, gas exchange stopped. We used the equation initially developed by Kooyman (1973), to estimate TLC (\( TLC_{est} = 0.135 M_b^{0.92} \), where \( M_b \) is body mass in kg), and later validated for the dolphin (Fahlman et al., 2011, 2015). Dead space volume was assumed to be 7% of TLC (Kooyman, 1973; Fahlman et al., 2011). The relationship between pulmonary shunt and \( DV_A V_A^{-1} \) was determined using a power function (Bostrom et al., 2008) for data from the harbor seals (Equation 6A in Fahlman et al., 2009).

All pressures were corrected for water vapor pressure, assuming that the respiratory system was fully saturated at 37°C.

### Blood and Tissue Gas Stores

As in previous studies, the blood and tissue stores of \( N_2, CO_2, \) and \( O_2 \) were determined by the solubility coefficients for each gas, as previously detailed (Fahlman et al., 2006). For \( O_2 \) and \( CO_2 \), the average concentration of hemoglobin for each population was used to estimate the blood \( O_2 \) stores and \( CO_2 \) storage capacity (Table 2). Tissue gas content was determined as previously detailed (Fahlman et al., 2006, 2009).

### Compartment Size, Cardiac Output, and Blood Flow Distribution

For the coastal ecotype sampled in Sarasota Bay, the relative size of each compartment was taken from previous studies in

---

**Table 1** Parameters used to describe the structural properties of the respiratory system.

| Parameter | Equation 4 | Equation 5 |
|-----------|------------|------------|
| \( a \)   | 1.05 ± 0.04 (1.1) |           |
| \( b \)   | 0.90 ± 0.06 (1.2) |           |
| \( c \)   | 2.51 ± 0.19 (1.3) |           |
| \( Kp \)  | −31.0 ± 23 (−12.8) |           |
| \( n \)   | 2.4 ± 1.4 (0.91) |           |

The parameters for Equations (4) and (5) in Bostrom et al. (2008) were revised using previously published compliance data from the bottlenose dolphin (Fahlman et al., 2018b). Old values are in parentheses.

**Table 2** Body compartment composition (% of body mass), estimated compartment metabolic rate (rest), and the value used in the model, cardiac output at rest/diving and at the surface, male adult dolphins.

coastal bottlenose dolphins (Table 2; Ridgway and Johnston, 1966; Mallette et al., 2016). For blood and muscle we used species-specific values for blood hematocrit (Ridgway and Johnston, 1966; Hall et al., 2007; Schwacke et al., 2009; Fahlman et al., 2018b), and myoglobin concentration (Noren et al., 2001; Ponganis, 2011). For the deep-diving offshore dolphins, we initially assumed that the animals were similar to the coastal ecotype from Sarasota Bay. However, these assumptions resulted in a cADL that was too short for all Bermuda dolphins. We therefore adjusted the body composition of the Bermuda dolphins, assuming that their body composition was similar to that of deep diving beaked whales (Pabst et al., 2016), and used the body composition for *Mesoplodon* from our previous studies (Table 2; Hooker et al., 2009).

For the current study, we assumed that the cardiac output (Q\text{tot}) at the surface was 3 times higher than the Q\text{tot} measured in resting bottlenose dolphins (31.5 ml min\(^{-1}\) kg\(^{-1}\), Miedler et al., 2015). To account for differences in Mb, mass specific Q\text{tot} (sQ\text{tot}) was adjusted using Equation (5) in Fahlman et al. (2009). During diving, the Q\text{tot} was reduced to 1/3 of the value at the surface to account for the dive response, i.e., the diving Q\text{tot} was the same as that measured in resting animals. Blood flow distributions to each tissue at the surface and during diving were iteratively tested to maximize utilization of O\text{2} to increase the aerobic dive duration (Table 2).

### Dive Data Used

We used dive data collected from high resolution digital audio and movement recording tags (DTAG, Johnson and Tyack, 2003) attached to the dorsal side of each dolphin by means of four small suction cups, and programmed to release after <24 h. DTAGs were deployed during 2013–2016 in Sarasota Bay and in...
August of 2016 off the coast of Bermuda, during capture-release operations (e.g., Wells et al., 2004; Klatsky et al., 2007). The dolphins were tagged and data collected under permits issued by NMFS (Scientific Research Permit Number 15543) and the Bermuda Government, Department of Environment and Natural Resources (Research permit number SP160401r).

Data processing was done using the DTAG toolbox (soundtags.st-andrews.ac.uk). Tag depth was sampled at 200 Hz and subsequently down-sampled to 25 Hz during post-processing using a linear phase 10 Hz low-pass FIR filter. Surfacings were used to estimate the zero-pressure offset and to characterize and remove the effect of temperature on estimated depth.

A dive was defined as a submergence deeper than 1.5 m (1.15 ATA) and longer than 10 s. The start and end of each dive was calculated as the first and last point of the dive that exceeded 0.1 m depth, and the surface interval was defined as the time from current dive to previous dive.

RESULTS

Respiratory Compliance

The updated parameters that defined the structural properties (compliance) of the respiratory system resulted in a stiffer upper airway and more compliant alveolar space as compared with the values used in previous studies (Figure 1A), which affected the pulmonary shunt (Figure 1B). The parameters for respiratory compliance were updated and the model output compared with the results from the previous model (Figures 1C, D). The end-dive gas tension increased with both dive duration and maximum dive depth for N\textsubscript{2} and O\textsubscript{2}, while for CO\textsubscript{2} there was a slight decrease (Figures 1C, D).

Dive Data

There were no significant differences in body mass (M\textsubscript{b}, P > 0.1, Welch t-value: 1.8, df = 2), body length (P > 0.9, t-value: 0.02, df = 5), average number of dives per hour (P < 0.1, Welch t-value: 0.3, df = 5), and average surface interval (P > 0.1, Welch t-value: 1.3, df = 2, Table 3) between ecotypes. There were significant differences in the dive behavior between the two populations, with dive duration (P < 0.01, Welch t-value: 4.37, df = 2), maximum dive depth (P < 0.05, Welch t-value: 3.95, df = 2), and mean depth per dive (P < 0.05, Welch t-value: 3.57, df = 2) being significantly higher in the Bermuda dolphins (Table 3, Figures 2, 3). For dives <60 s, the Sarasota dolphins never exceeded a dive depth of 5 m (Figure 3A). As the dive duration increased >60 s, so did the maximum depth and also the variation (Figure 3A). For the Bermuda dolphins, there was a significant increase in the dive duration as the dive depth increased (Figure 3B). Dives <60 s showed little variation and few exceeded 10 m (Figure 3B). As the dive duration increased beyond 100 s, the variation in maximum dive depth increased and dives exceeding 100 m became more common (Figure 3B). We found no indication that the surface interval increased with dive duration of the previous (X\textsuperscript{2} = 0.27, df = 1, P > 0.6) or next dive (X\textsuperscript{2} = 0.05, df = 1, P > 0.8).
Cardiac Output and Blood Flow Distribution

For both populations, we assumed that the diving $Q_{\text{tot}}$ was equal to resting values measured in the bottlenose dolphins (Table 4; Miedler et al., 2015). The blood flow distribution for the Sarasota dolphins was able to vary greatly, due to their shorter and shallower dive pattern. For the Bermuda dolphins, deviation from a certain blood flow distribution caused tissues to run out of $O_2$. The specific variation varied slightly between individual animals, but one distribution pattern that focused perfusion to the central circulation, and minimized flow to the muscle, allowed all dolphins to complete their dives aerobically (Table 4).

The blood flow required at the surface to assure that tissues received enough blood to restore $O_2$ stores at the surface differed between the two ecotypes. For the Sarasota dolphins, the minimum $Q_{\text{tot}}$ at the surface was 3 times higher than during diving. A surface $Q_{\text{tot}}$ at least 7 times higher than during diving was required for the Bermuda population to ensure that tissues were saturated with $O_2$; any lower surface $Q_{\text{tot}}$ would result in tissue $PO_2$ continuously decreasing with each dive. In addition, for the Bermuda dolphins, changes in perfusion associated with diving, i.e., the dive response, was set to occur only for dives deeper than 20 m. Consequently, the elevated $Q_{\text{tot}}$ was required at the surface to help restore blood and tissue $O_2$ stores.

Blood and Tissue Gas Tensions

In the Sarasota dolphins, there was considerable variation in end-dive blood and tissue $PO_2$ with dive duration. In Figure 4, the muscle is used as a representative tissue to show these variations. In Figure 4A, the large variation in muscle $PO_2$ is shown when the muscle tension is plotted against dive duration. There was a consistent exponential decrease with dive depth (Figure 4B). A decrease in the blood and tissue $PO_2$ was obvious in the Bermuda dolphins for both dive duration (Figure 4C) and depth (Figure 4D). For the Bermuda dolphins, the decrease in tissue $PO_2$ varied depending on the level of pulmonary shunt, and the shunt decreased the end dive $PO_2$ for dives of the same duration or maximum depth (Figures 4C, D). The effect of the shunt on end-dive $PO_2$ was most obvious for the muscle compartment, but was also seen in the other tissues (data not shown).
The estimated blood and tissue PO$_2$ for a representative dive for dolphins from Sarasota (Figure 5A) or Bermuda (Figure 5B) showed similar patterns of a decrease in PO$_2$ during a dive. However, the longer and deeper dive duration resulted in greater changes in blood and tissue PO$_2$ values in the offshore ecotype. Figures 5C,D show the effect of depth on lung volume and pulmonary shunt.

**DISCUSSION**

In the current study, we modeled tissue and blood PO$_2$, PCO$_2$, and PN$_2$ from fine-scale empirical dive data from bottlenose dolphins of both the coastal and offshore ecotypes to assess potential morphological or physiological adaptations that could help explain the large variation in dive behavior in these divergent populations. The results show that the structural properties of the respiratory system have a significant effect on pulmonary gas exchange, and these changes are different for gases with different gas solubilities, agreeing with past work suggesting that variation in ventilation and perfusion may be important for managing gases during diving (West, 1962; Farhi and Yokoyama, 1967; Hodanbosi et al., 2016; García Párraga et al., 2018). Furthermore, the results suggest that the deeper and longer dives of the offshore dolphins most likely reflect a greater O$_2$ storage capacity, potentially combined with foraging of lower energetic cost. Future tagging studies to assess the energetic requirements of the different foraging strategies will be crucial to assess how close to their physiological limits each of these populations are living.

Theoretical work has suggested that the level of gas exchange, $\dot{Q}_{\text{tot}}$, and blood flow distribution are important to alter blood and tissue gas levels (Fahlman et al., 2006, 2009). Previously, we suggested that the structural properties of the respiratory system could have a significant effect on the level of gas exchange during breath-hold diving (Bostrom et al., 2008; Fahlman et al., 2009), and how man-made disturbances may alter the risk of gas emboli through changes in the dive profile or physiology (Hooker et al., 2009; Kvadsheim et al., 2012). However, species-specific estimates for the structural properties of the respiratory system were not available and published values from a range of species were used (Bostrom et al., 2008; Fahlman et al., 2009, 2014; Hooker et al.,...
2009; Kvadsheim et al., 2012), but recent work has suggested that species-specific estimates may significantly alter the model estimates (Hodanbosi et al., 2016). We therefore used recently published data for respiratory compliance (Fahlman et al., 2011, 2015, 2018b), \( Q_{\text{tot}} \) (Miedler et al., 2015), and metabolic rate (Fahlman et al., 2015, 2018a) for coastal and offshore bottlenose dolphin to update the model parameters. These changes altered the compression of the alveolar space, which affects the pressure dependence of the pulmonary shunt (Figure 1).

The updated parameters (Table 1), with stiffer airways and more compliant alveolar space, increased the level of shunt and reduced gas exchange throughout dives (Figures 1A,B). This significantly reduced N\(_2\) exchange during deeper dives as the alveolar space began compressing (Figures 1C,D). The updated parameters also affected O\(_2\) exchange, but the effect was less apparent. For CO\(_2\) there was little effect, and for longer and deeper dives, CO\(_2\) exchange was improved. This implies that variation in gas exchange from changes in the alveolar ventilation (\( V_A \)) and \( Q_{\text{tot}} \) relationship (\( V_A/Q_{\text{tot}} \)) differs for gases with varying gas solubility (West, 1962; Farhi and Yokoyama, 1967). These results agree with theoretical modeling in California sea lions that showed that changes in the structural properties of the respiratory system have a significant effect on the exchange of O\(_2\), CO\(_2\), and N\(_2\) that differs between gas species (Hodanbosi et al., 2016). Together these studies provide additional support for a recent hypothesis suggesting that the lung architecture and varying \( V_A/Q_{\text{tot}} \) relationship, e.g., the effect of heterogeneous pulmonary blood flow and alveolar compression (collateral ventilation), it shows that varying the structural properties, which effectively reduces the \( V_A/Q_{\text{tot}} \), the less soluble (N\(_2\)) is significantly more
affected as compared with the more soluble gases (O\textsubscript{2} and CO\textsubscript{2}) (West, 1962; Farhi and Yokoyama, 1967). Thus, increasing upper airway stiffness and making the alveolar space more compliant causes the compression to occur at shallower depth, as originally hypothesized by Scholander (1940). This increases the level of shunt and reduces diffusion/ventilation, which has the greatest effect on gas with low solubility (West, 1962; Farhi and Yokoyama, 1967). In summary, we propose that the data in the current study agree with the suggestion that varying the \( \frac{V_A}{Q_{\text{tot}}} \) ratio may be an efficient way for deep divers to minimize N\textsubscript{2} while still accessing pulmonary O\textsubscript{2} and CO\textsubscript{2} (García Párraga et al., 2018).

The dive behaviors for the two dolphin forms were strikingly different, and demonstrate the large physiological plasticity in cetacean ecotypes. While these differences in dive behavior are undoubtedly related to differences in morphology, physiology and environment, the data presented here provide an interesting comparison of a species’ capacity to vary physiological traits. Initially we used the available information for coastal dolphins to model tissue and blood gas dynamics in both populations (Table 2). For a 200 kg dolphin, the estimated O\textsubscript{2} stores were 8.7 l (43.6 ml O\textsubscript{2} kg\(^{-1}\)), resulting in a calculated aerobic dive limit (cADL) of 6.5 min when assuming a field metabolic rate that is twice that of resting. This cADL is considerably greater than the observed maximum dive durations in the Sarasota dolphins ranging from 2.2 min in the current study (Table 3), or up to 4.5 min in previous work (R. Wells, unpublished observation, Wells et al., 2013). The diet of bottlenose dolphins in Sarasota is composed exclusively of fish (> 15 different species found in stomach content of 16 stranded animals; Barros and Wells, 1998). Thus, their activity may require a variety of high energy activities from rapid body turns (pinwheel feeding) to tail slaps (fish whacking, kerplunking) associated with prey capture (Nowacek, 2002), which would increase the daily metabolic rate and reduce the cADL. For a cADL of 2.2–4.5 min, the Sarasota ecotype would have a metabolic scope around 3–6 times their resting metabolic rate (3 times the estimated field metabolic rate in Table 3). The metabolic scope is the maximal aerobic metabolic rate divided by the basal metabolic rate and is typically in the range of 3–10; a scope > 7 cannot be sustained over long periods (Peterson et al., 1990). Thus, a field metabolic rate that is 6 times higher than the resting value implies that this ecotype would be working at or close to the maximal aerobic capacity for a cADL of 2.2 min. However, another likely explanation is that the coastal dolphins here operate in an environment where they are seldom limited by their dive physiology. The bottlenose dolphins from which dive data were obtained primarily occupy shallow waters in and around Sarasota and Palm Sola bays, with water depths generally < 10 m, and often less than a few meters. Thus, our results suggest that they can significantly increase their dive duration if necessary but that they may not need this to exploit prey in their shallow-water habitat.

The Bermuda dolphins, on the other hand, had significantly longer dives than the Sarasota animals. A considerable number of dives exceeded the cADL, even when calculated from twice the resting metabolic rate, and the dolphin ran out of O\textsubscript{2} during long dives. For this reason, we hypothesized that the offshore dolphins must have increased O\textsubscript{2} stores to help increase their dive duration. We are not aware of any published body composition data for offshore dolphins, and to increase the O\textsubscript{2} stores we therefore modeled the body compartments according to the proposed body composition for deep-diving beaked whales, with increased blood and muscle O\textsubscript{2} storage (Peterson et al., 1990) that significantly increased the total O\textsubscript{2} stores (98.6 ml O\textsubscript{2} kg\(^{-1}\)), and the cADL (18.2 min, Table 2). With a maximal dive duration of 9 min, this provided a considerable scope for the Bermuda dolphins. The O\textsubscript{2} storage capacity of the sperm whale (81 ml O\textsubscript{2} kg\(^{-1}\)), hooded seal (90 ml O\textsubscript{2} kg\(^{-1}\)), elephant seal (94 ml O\textsubscript{2} kg\(^{-1}\)), and Weddell seal (89 ml O\textsubscript{2} kg-1, Ponganis, 2015) are lower than our estimated value. The calculations made in the current study are based on assumptions about the blood volume, and muscle mass of these animals, and it is likely that the O\textsubscript{2} storage capacity is lower and the cADL shorter. If we assume that the longest dive represent the upper limit of the cADL, we would need an O\textsubscript{2} storage capacity of approximately 49 ml O\textsubscript{2} kg\(^{-1}\)). Thus, we can predict that the O\textsubscript{2} storage capacity is somewhere between these two values for the offshore ecotype.

In addition to a greater O\textsubscript{2} storage capacity, Bermuda dolphins may also have a greater capacity to alter diving metabolic rate. In a previous study, we estimated the field metabolic rate of coastal ecotype bottlenose dolphins to be around 11.7–23.4 ml O\textsubscript{2} min\(^{-1}\) kg\(^{-1}\), the blood O\textsubscript{2} stores used could be used to determine how energy is partitioned in this population and resolve some of these questions. In fact, the DTAG data provide such an opportunity and is an objective for future studies.

The dive data from the Bermuda dolphins are suggestive of 2 different types of dives; one shallow (10–70 m, Figure 3B) that changes little in depth with duration and another dive type starting at around 100 m depth with a steep increase in dive duration with depth (Figure 3B). It is not surprising that deeper dives are generally longer, as the transit to depth is a significant portion of the dive duration. During the deeper dives, the pulmonary shunt alters the blood and tissue gas content, as shown for the end-dive muscle PO\textsubscript{2} in Figure 4C. Without access to pulmonary PO\textsubscript{2}, the blood O\textsubscript{2} was reduced and more O\textsubscript{2} used from the muscle, pushing down end-dive PO\textsubscript{2}. This was not seen in the shallow diving Sarasota dolphins (Figure 4A), which never dive to depths where the pulmonary shunt began to alter gas tensions.
The differences in dive behavior had a significant effect on the gas tension in the blood and tissues (Figure 5). For both populations there was a continuous decrease in blood gases during the dive but the decrease was more extreme for the Bermuda dolphins (Figure 5B), and matching the blood flow to various tissues was more restrictive. This agrees with the suggestion made in previous modeling work that an important aspect of the dive response is to distribute the available perfusion to central tissues like the heart and brain, while blood flow to the muscle should be minimal (Davis and Kanatous, 1999). This allows muscle metabolism to be fueled by endogenous O\textsubscript{2} and assures that the matching of utilization of endogenous and vascular O\textsubscript{2} increases the duration of the dive that is fueled by aerobic metabolism (Davis and Kanatous, 1999).

For both ecytypes, the Q\textsubscript{tot} while diving was assumed equal to the resting value measured in bottlenose dolphins (Miedler et al., 2015). The surface Q\textsubscript{tot} in the Sarasota ectype was set to 3 times higher than resting, which sufficiently restored O\textsubscript{2} and removed CO\textsubscript{2} from the blood and tissues to avoid continuous changes with repeated dives. In the Bermuda animals, on the other hand, a surface Q\textsubscript{tot} of 3 times resting was not sufficient to restore the O\textsubscript{2} or remove the CO\textsubscript{2} during the longer dives. Initially, Q\textsubscript{tot} was increased to 7 times higher than during diving, but while this improved restoration of blood and tissue O\textsubscript{2} and CO\textsubscript{2} levels, there were still continuous changes with repeated dives. By keeping the Q\textsubscript{tot} elevated for submersions <20 m, however, we were able to sufficiently restore O\textsubscript{2} and remove enough CO\textsubscript{2} to prevent accumulating changes across repeated dives. These results suggest that Q\textsubscript{tot} needs to be maintained during intervening short and shallow dives to allow restoration of normal blood and tissue gas tensions. Staying submerged during this time may help increase the PO\textsubscript{2} and thereby the uptake of O\textsubscript{2}. The suggestion that there is little or no cardiovascular modification during shallow dives may be controversial, as most studies have reported changes in heart rate during diving. For example, in the bottlenose dolphin resting at the surface or while submerged the average heart rate were 105 and 40 beats min\textsuperscript{-1}, respectively (Noren et al., 2012). However, the past study provides an estimated surface resting heart rate that is influenced by the respiratory sinus arrhythmia (RSA), which will significantly elevate the resting values. In a more recent paper the surface resting heart rate when accounting for the RSA ranged from 27 to 54 beats min\textsuperscript{-1} (Miedler et al., 2015), thus not very different from the resting diving heart rate reported by Noren et al. (2012). In addition, in the past study it was also reported that the diving heart rate increased with underwater activity by at least 40 and 79\% (Noren et al., 2012). While our estimated Q\textsubscript{tot} at depths shallower than 20 m may be overestimated, there is experimental evidence that the perfusion is modulated while submerged and future studies could look at how this changes during short and shallow dives.

In the Sarasota dolphins, the dive depth caused a reduction in alveolar volume, but the low pressure did not cause tracheal compression or induce a pulmonary shunt (Figure 5C). In the Bermuda dolphins, the arterial PO\textsubscript{2} increased during the descent to a maximum value, and then rapidly declined until the alveoli were reinflated during the ascent at which a second peak was observed (Figure 5B). We previously suggested that this pattern of arterial gas tension would support Scholander's hypothesis of pressure-induced hyperoxia as the lungs are compressed, followed by an increasing shunt as the alveoli are compressed until atelectasis (alveolar collapse), in this case at 126 m (Figure 5D), when the arterial side reflects the mixed venous (Fahlman et al., 2009; McDonald and Ponganis, 2012). This is supported by empirically measured arterial and venous gas tensions in both seals (Falke et al., 1985) and sea lions (McDonald and Ponganis, 2012). As the dolphin ascends, the alveoli are recruited at a depth of 126 m and gas exchange commences again. At this point, there is a second peak as pulmonary O\textsubscript{2} again saturates the blood (Figures 5C,D). The second peak for arterial PO\textsubscript{2} is lower as compared with the peak right before atelectasis, despite equivalent pulmonary PO\textsubscript{2}. During the dive, the O\textsubscript{2} in the blood is continuously consumed, causing both the arterial and venous PO\textsubscript{2} to decrease. As the alveoli are recruited at depth, the pulmonary PO\textsubscript{2} increases. The high pulmonary and low venous PO\textsubscript{2} result in an elevated partial pressure gradient that favors diffusion and gas exchange. Thus, pulmonary O\textsubscript{2} diffuses into the pulmonary capillary and helps saturate the arterial blood. In addition, CO\textsubscript{2} is removed from the blood into the lung. Both these processes help prepare the dolphin to minimize the duration of the surface interval as CO\textsubscript{2} is being removed and O\textsubscript{2} being taken up before reaching the surface. Elevated gas exchange at depth also increases N\textsubscript{2} exchange, increasing the tissue and blood tension and the risk for gas emboli. However, the elevated pulmonary pressure as the alveoli open results in an elevated V\textsubscript{A}/Q\textsubscript{tot} ratio, favoring O\textsubscript{2} and CO\textsubscript{2} exchange, while limiting N\textsubscript{2} exchange (García Párraga et al., 2018). In addition, it has been hypothesized that marine mammals are able to separate the lung into two regions; one region that is ventilated and another atelecatic area, with the latter being perfused (García Párraga et al., 2018). This matching of pulmonary blood flow to hypoxic/atletic regions result in selective gas exchange (Olson et al., 2010; García Párraga et al., 2018), which during normal dives would help reduce the risk for gas emboli, and help prepare the dolphin to restore the O\textsubscript{2} used and removing the CO\textsubscript{2} produced (West, 1962; Farhi and Yokoyama, 1967; Olson et al., 2010). There is also evidence for an arterio-venous shunt that alters the blood gas tensions and could help minimize inert gas uptake during the ascent and help arterialize venous blood (García Párraga et al., 2018).

In a number of marine mammals, there is an anticipatory presurfacing tachycardia, which likely increases Q\textsubscript{tot} (Fedak et al., 1988; Thompson and Fedak, 1993; Andrews et al., 1997; Noren et al., 2012; Williams et al., 2017). During natural undisturbed dives, it seems that the change in heart rate begins during the initial stages of the ascent, but a large increase occurs during the later stages of the ascent close to the surface. Close to the surface, the blood and tissue tension could be supersaturated with N\textsubscript{2} and the gas would move from the tissues to the lungs (Fahlman et al., 2009). Elevated Q\textsubscript{tot} at this stage of the dive would result in a decrease in the V\textsubscript{A}/Q\textsubscript{tot} ratio, which would enhance exchange and removal of N\textsubscript{2}. It has been hypothesized that disturbance of normal diving homeostasis, such as exposure to man-made
sound, capture in nets, or any stressful situation may alter the physiology and result in conditions that enhance N₂ uptake and the risk for gas emboli (Fernandez et al., 2005; Hooker et al., 2009; Fahlman et al., 2014; García-Párraga et al., 2014). In turtles, it has been suggested that the stress associated with incidental capture in fishing gear result in a sympathetic response, which opens the arterial pulmonary sphincter, increases pulmonary blood flow, decreases the \( V_A/Q_{tot} \) ratio and increase N₂ uptake and risk of gas emboli (García-Párraga et al., 2014, 2017; Fahlman et al., 2017a). In cetaceans, active management of the pulmonary physiology and result in conditions that enhance N₂ uptake and risk of gas emboli (Fahlman et al., 2006; Hooker et al., 2009). Theoretical modeling has indicated that stress related changes in \( Q_{tot} \) may increase the risk for gas emboli, and empirical data in the narwhal indicate that the large changes in the diving heart rate occurs deeper under stressful situations (around 170 m) as compared with natural dives (Fahlman et al., 2009, 2014; Hooker et al., 2009; Williams et al., 2017). Thus, this reversal of the diving bradycardia may result in elevated pulmonary blood flow, changes in blood flow distribution within the lung and changes in \( V_A/Q_{tot} \) resulting in elevated N₂ uptake and risk for gas emboli (Garcia Párraga et al., 2018).

In summary, in the current study we show that the dive behavior in deep diving bottlenose dolphins likely requires morphological differences resulting in a greater O₂ storage capacity as compared with the coastal ecotype. It is also possible that the foraging behavior of the offshore population, with longer periods of gliding, results in lower foraging metabolic costs. Our results also indicate the importance of species-specific data when predicting physiological responses of animals. By updating the compliance estimates for the respiratory system, we show additional evidence of how variation in the ventilation/perfusion relationship is able to alter exchange of gases. This result provides additional support for our hypothesis of how marine mammals manage gases during diving and how stress may alter physiology and cause increased N₂ uptake and risk of gas emboli from forming.

**DATA AVAILABILITY**

The theoretical model and data used in this paper are made freely available at: osf.io/eyxp.

**AUTHOR CONTRIBUTIONS**

AF helped collect the dive data, performed the modeling work, data analysis, wrote the first draft of the paper. FHJ collected and extracted the dive data, and helped edit the paper. PT provided the tools to collect the dive data, and helped edit the paper. RW helped collect the dive data and edited the paper.

**FUNDING**

AF (N00014-17-1-2756), PT (N000141512553) and FHJ (N00014-14-1-0410) were supported by the Office of Naval Research, and FHJ by an AIASTOFUND fellowship from Aarhus Institute of Advanced Studies, Aarhus University, under EU’s FP7 program (Agreement No. 609033). PT received funding from the MASTS pooling initiative (The Marine Alliance for Science and Technology for Scotland) and their support is gratefully acknowledged. MASTS is funded by the Scottish Funding Council (grant reference HR09011) and contributing institutions. Funding for the Sarasota Bay and Bermuda field-work was provided by Dolphin Quest, Inc., and Office of Naval Research (N00014-14-1-0563).

**ACKNOWLEDGMENTS**

A special thanks to many volunteers and staff at Dolphin Quest and the Sarasota Dolphin Research Project who made collection of the dive data possible. A special thanks to Nigel Pollard, the Bermuda Government, the Bermuda Aquarium, Museum and Zoo (BAMZ), and NOAA.
