The transmission of matter wave solitons through linear and nonlinear inhomogeneities induced by the spatial variations of the trap and the scattering length in Bose-Einstein condensates are investigated. New phenomena, such as the enhanced transmission of a soliton through a linear trap by a modulation of the scattering length, are exhibited. The theory is based on the perturbed Inverse Scattering Transform for solitons, and we show that radiation effects are important. Numerical simulations of the Gross-Pitaevskii equation confirm the theoretical predictions.

I. INTRODUCTION

The transmission of matter wave packets through inhomogeneities of different types of Bose-Einstein condensates (BECs) has recently attracted a lot of attention, because this phenomenon is important for the design of control methods of the soliton parameters and atomic soliton lasers [1]. The transmission and reflection of bright and dark matter solitons has been studied in the case of linear inhomogeneities, induced by the variations in space of the potential field [2 2 2 2]. The effect of a potential step or impurity, including the soliton train evolution, has been analyzed in [2]. The case of inhomogeneities produced by spatial variations of the scattering length has been less investigated [2 2 2 9]. Numerical simulations of the problem of soliton propagation have been carried out, when the linear and nonlinear inhomogeneities compete with each other. It was found that for some choices of parameters the enhanced transmission of soliton through the nonlinear barrier is possible [11].

The purpose of this work is to develop the theory describing the transmission of matter wave solitons through nonlinear barriers. Such barriers can be produced by using the Feshbach resonance method, namely by the local variation of the external magnetic field \( B(x) \) in space near the resonant value \( B \). [11]. By the small variation of the field near the resonant value we can induce the large variations of the scattering length in space according to the formula

\[
a_s(x) = a_b \left( 1 - \frac{\Delta}{B_c - B(x)} \right),
\]

where \( a_b \) is the background value of the atomic scattering length and \( \Delta \) is the resonance width. Optical methods for manipulating the value of the scattering length are also possible [12]. As a result, the mean field nonlinear coefficient (which is proportional to the scattering length \( a_s \)) in the Gross-Pitaevskii equation has a spatial dependence. We will use the perturbed Inverse Scattering Transform theory (see for example [13 14 15]) to describe the transmission of bright matter wave solitons through the nonlinear barriers. This approach allows us to analyze the adiabatic dynamics of solitons as well as the radiative processes during the soliton propagation through inhomogeneities.

II. THE MODEL

The quasi one-dimensional Gross-Pitaevskii (GP) equation describing the wavefunction of BEC in an elongated trap has the form [10]

\[
i\hbar \psi_t + \frac{\hbar^2}{2m} \psi_{xx} - V(x) \psi - g_{1D}(x)|\psi|^2 \psi = 0.
\]

Here \( g_{1D}(x) = 2\hbar \omega_{\perp} a_s(x) \), where \( \omega_{\perp} \) is the transverse oscillator frequency, \( a_s(x) \) is the spatially dependent atomic scattering length, and \( V(x) \) is the linear potential. Both \( a_s(x) \) and \( V(x) \) are assumed to be constant outside a given domain, where we assume that the scattering length takes the constant negative value \( a_{s0} \) and \( V \) is zero, \( \int |\psi|^2 dx = N \), where \( N \) is the number of atoms. We denote by \( g_{1D} = 2\hbar \omega_{\perp} a_{s0} \) the reference value of the nonlinear coefficient.

From now on we express \( x \) in units of the healing length \( \xi = \hbar/\sqrt{\pi \alpha_{1D} m} \) and \( t \) in units of \( t_0 = \xi/(2c) \), where \( c = \alpha_{1D} m / m \) is the Bogoliubov speed of sound and \( n_0 \) the peak density. We also normalize the mean field wavefunction by \( \sqrt{n_0} \), so that we obtain the dimensionless GP equation in the form of the Nonlinear Schrödinger (NLS) equation

\[
iu_t + u_{xx} + \gamma(x)|u|^2 u - V_l(x)u = 0,
\]

with \( \gamma(x) = 2 - V_{nl}(x) = 2a_s(x)/a_{s0} \). If \( V_l = V_{nl} = 0 \), then this equation can be reduced to the standard NLS equation that supports soliton solutions. The bright soliton solution is:

\[
u_s(x,t) = 2\nu \text{sech}[2\nu(x-x_s(t))] \exp[2i\mu(x-x_s(t))+i\phi_s(t)].
\]

†† Corresponding author (garnier@math.jussieu.fr)
The soliton amplitude is $2\nu$ and its velocity is $4\mu$. The soliton center and phase $x_s(t)$ and $\phi_s(t)$ satisfy
\[
\frac{dx_s}{dt} = 4\mu, \quad \frac{d\phi_s}{dt} = 4(\nu^2 + \mu^2).
\]
The matter wave soliton moving in the linear and nonlinear potentials $V_l$ and $V_{nl}$ experiences velocity and mass modulations and emits radiation. To describe this process we use the perturbation theory based on the Inverse Scattering Transform (IST).

### III. QUASI-PARTICLE APPROACH

Applying the first-order perturbed IST theory, we obtain the system of equations for the soliton amplitude and velocity
\[
\frac{d\nu}{dt} = 0, \quad \frac{d\mu}{dt} = -\frac{1}{4\nu} W'(\nu, x_s), \quad \frac{dx_s}{dt} = 4\mu,
\]
where the prime stands for a derivative with respect to $x$ and the effective potential has the form
\[
W(\nu, x) = W_l(\nu, x) + W_{nl}(\nu, x),
\]
with
\[
W_l(\nu, x) = \nu \int_{-\infty}^{\infty} \frac{1}{\cosh^2(z)} V_l(z/2\nu + x) dz, \quad (3)
\]
\[
W_{nl}(\nu, x) = 2\nu^3 \int_{-\infty}^{\infty} \frac{1}{\cosh^4(z)} V_{nl}(z/2\nu + x) dz. \quad (4)
\]
We can thus write the effective equation describing the dynamics of the soliton center as a quasi-particle moving in the effective potential $W$:
\[
\nu_0 \frac{d^2 x_s}{dt^2} = -W'(\nu_0, x_s), \quad (5)
\]
where $4\nu_0$ is the mass (number of atoms) of the incoming soliton. This system has the integral of motion
\[
\frac{\nu_0}{2} \left( \frac{dx_s}{dt} \right)^2 + W(\nu_0, x_s) = 8\nu_0\mu_0^2, \quad (6)
\]
where $4\mu_0$ is the velocity of the incoming soliton. Note that this approach is standard and it was recently applied in [15]. In this work, it is the first step as we will include second-order and radiation effects in the next section. Let us briefly discuss the main results that can be obtained with the quasi-particle approach.

**Barrier potential.** Let us first examine the case where the potential $V$ is a barrier, meaning that $V \geq 0$ and $\lim_{|x| \to \infty} V(x) = 0$. When the soliton approaches the barrier, it slows down, and it eventually goes through the barrier if its input energy is above the maximal energy barrier, meaning $8\nu_0\mu_0^2 > W_{max}(\nu_0)$. For a linear barrier potential which is an even function, we have $W_{max}(\nu) = W_l(\nu, 0)$, where $W_l$ is given by (3). For a nonlinear barrier potential which is an even function, we have $W_{max}(\nu) = W_{nl}(\nu, 0)$. After passing through the barrier, the soliton recovers its initial mass and velocity. In that sense, the transmission coefficient is one.

If, on the contrary, the velocity of the incoming soliton is such that $8\nu_0\mu_0^2 < W_{max}(\nu_0)$, then the soliton is reflected by the barrier. After the interaction with the barrier, the soliton recovers its initial mass and velocity.

**Trap potential.** We now examine the case where the potential is a trap, meaning that $V \leq 0$ and $\lim_{|x| \to \infty} V(x) = 0$. When the soliton approaches the trap, it speeds up, and it eventually goes through the barrier whatever its initial velocity is. This is the prediction of the quasi-particle approach. However, we shall see that the interaction with the trap generates radiation and reduces the mass and energy of the soliton. As a result, the soliton may not be able to escape the trap if its initial velocity is too small. We shall discuss this point in the next section.

### IV. RADIATION EFFECTS

The properties of the radiation emitted by the soliton interacting with the inhomogeneities are defined by the Jost coefficients $a(t, \lambda)$ and $b(t, \lambda)$ of the associated linear spectral problem for the NLS equation [13 14 15]. We assume that the linear and nonlinear potentials are localized functions, and we denote by $V(k) = \int_V(x) \exp(ikx) dx$ their Fourier transforms. If the soliton goes through the potential, then we find
\[
b(t = +\infty, \lambda) = \frac{-i\pi(\lambda - \mu - i\nu)^2}{16\mu^4 \cosh^2 \left( \frac{x^2 + \nu^2 - \mu^2}{2\mu} \right)} \times \left[ \tilde{V}_l(k(\lambda, \nu, \mu)) + \frac{[(\lambda + \mu)^2 + \nu^2][(\lambda - 3\mu)^2 + 8\mu^2 + \nu^2]}{12\mu^2} \tilde{V}_{nl}(k(\lambda, \nu, \mu)) \right]
\]
where
\[
k(\lambda, \nu, \mu) = \frac{(\lambda - \mu)^2 + \nu^2}{\mu}
\]
and the total radiated mass density during the interaction with the potentials is
\[
n(\lambda) \simeq \frac{1}{\pi} \frac{b}{a}(t = +\infty, \lambda)^2
\]
The total mass (number of atoms) and Hamiltonian are preserved:

\[
N = \int_{-\infty}^{\infty} |u|^2 \, dx
\]

\[
H = \int_{-\infty}^{\infty} \left[ |u_x|^2 - |u|^4 + V_l(x)|u|^2 + \frac{1}{2} V_{nl}(x)|u|^4 \right] \, dx.
\]

They can be expressed in terms of the radiation and soliton components as

\[
N = 4 \nu + \int_{-\infty}^{\infty} n(\lambda) \, d\lambda,
\]

\[
H = 16 \nu \mu^2 - \frac{16}{3} \nu^3 + 2 W(\nu, x) + 4 \int_{-\infty}^{\infty} \lambda^2 n(\lambda) \, d\lambda.
\]

Note that this expression of the Hamiltonian generalizes the expression of the energy \(E\). The coefficients \((\nu_T, \mu_T)\) of the transmitted soliton are

\[
\nu_T = \nu_0 - \frac{1}{4} \int_{-\infty}^{\infty} n(\lambda) \, d\lambda, \quad (7)
\]

\[
\mu_T = \mu_0 - \frac{1}{8} \int_{-\infty}^{\infty} \left( \frac{\lambda^2}{\mu_0 \nu_0} + \frac{\nu_0}{\mu_0} - \frac{\mu_0}{\nu_0} \right) n(\lambda) \, d\lambda. \quad (8)
\]

These formulas allow us to study and characterize the transmission of a soliton through a general barrier in various regimes. We can consider the transmission/reflection of a bright soliton through a nonlinear barrier, the transmission/trapping in a nonlinear trap, and competition effects for the transmission through the superposition of nonlinear and linear potentials.

In the next subsections, we compare our theoretical predictions with results from numerical simulations of the one-dimensional GP equation, with a Gaussian linear potential and/or a nonlinear Gaussian potential:

\[
V_l(x) = V_{l0} \exp \left( -\frac{x^2}{x_c^2} \right), \quad V_{nl}(x) = V_{nl0} \exp \left( -\frac{x^2}{x_c^2} \right).
\]

We consider the transmission of a soliton incoming from the left homogeneous half-space with parameters \((\nu_0, \mu_0)\). We plot the variations of the soliton parameters versus the value of the velocity for \(\nu_0 = 0.5\) and \(x_c = 0.5\). We consider different combinations of linear and nonlinear potentials.

**Nonlinear barrier.** We consider the case \(V_{l0} = 0\) and \(V_{nl0} > 0\). We have seen in Section III that the condition for the transmission through a nonlinear barrier is that the velocity of the incoming velocity is large enough so that \(8\nu_0 \mu_0^2 > W_{\text{max}}(\nu_0)\). Note that this means that the critical velocity parameter \(\mu_{\text{crit}}\) defined by the identity \(8\nu_0 \mu_{\text{crit}}^2 = W_{\text{max}}(\nu_0)\), is of the order of \(V_{nl0}^{1/2}\) for \(V_{nl0} \ll 1\). If the transmission condition fails, then the soliton is reflected.

These results are obtained in the quasi-particle approach and neglect the radiation emission phenomenon.
tion with the barrier, the soliton velocity is about $4\mu_{\text{max}}$, so the energy loss can be estimated by $-4 \int \lambda^2 n(\lambda) d\lambda$, where $\mu_{\text{max}}$ is substituted for $\mu_0$ in the expression of $b/a$. If a negative value $\mu_T$ is obtained in (9), then this means that the soliton has not been transmitted, but was trapped by the nonlinear potential (see Figure 2). Note that $n(\lambda) \sim V_{nl0}^2$ so that the critical value $\mu_{\text{crit}}$ for trapping is of the order of $V_{nl0}$.

If the initial velocity is large enough to ensure transmission, then the soliton emits radiation and looses mass. The mass loss is described by (7) and it is of the order of $V_{nl0}$ for $V_{nl0} \ll 1$.

**Enhanced transmission by nonlinear modulation.** As pointed out in [17], the nonlinear potential $V_{nl}$ can help a soliton going through a trap potential $V_f$. We illustrate this assertion based on numerical experiments in this section and justify it with our perturbed IST approach.

By comparing the transmission through a linear trap in presence or in absence of a nonlinear positive potential, we confirm the numerical conjecture that the transmission coefficient can be significantly increased by a nonlinear modulation (see Figures 3-4). In fact, the radiation emitted by the soliton due to the interaction with the linear trap and with the nonlinear potential can cancel each other, resulting in an enhanced soliton transmittivity.

A similar result can be obtained with a linear barrier. A nonlinear negative modulation can help the soliton go-

---

**FIG. 2:** Soliton parameters variations versus input velocity parameter $\mu_0$ for a nonlinear trap. The theoretical trap condition is $\mu_T < 0$ which gives $\mu_{\text{crit}} = 0.12$ for $V_{nl0} = -1$ and $\mu_{\text{crit}} = 0.07$ for $V_{nl0} = -0.5$. The agreement with the simulations is noticeable for $V_{nl0} = -0.5$, while the case $V_{nl0} = -1$ is only in qualitative agreement with the simulations.

**FIG. 3:** Soliton parameters variations versus input velocity parameter $\mu_0$ for a linear trap. The theoretical trap condition is $\mu_T < 0$ which gives $\mu_{\text{crit}} = 0.15$ for $V_0 = -1$ and $\mu_{\text{crit}} = 0.1$ for $V_0 = -0.5$, in good agreement with the simulations in the case $V_0 = -0.5$.

**FIG. 4:** Soliton parameters variations versus input velocity parameter $\mu_0$ for a linear trap superposed with a nonlinear barrier. The theoretical trap condition is $\mu_T < 0$ which gives $\mu_{\text{crit}} = 0.08$ for $V_{nl0} = 1$, $V_0 = -1$ and $\mu_{\text{crit}} = 0.04$ for $V_{nl0} = 0.5$, $V_0 = -0.5$, in good agreement with the simulations in the case $V_{nl0} = 0.5$, $V_0 = -0.5$. 

ing through the linear barrier by reducing the radiation emission and by reducing the minimal velocity reached by the soliton during the interaction. This was predicted by numerical simulations in [11].

For consistency we propose an experimental configuration where the enhanced transmission could be observed for the $^7$Li condensate. The transverse frequency $\omega_{\perp} \approx 2\pi \times 10^3$ Hz and the density is $n = 10^9$ m$^{-3}$. The healing length and speed of sound are $\xi \approx 2 \mu$m and $c \approx 5$ mm/s, respectively. As a typical experiment, we could consider a soliton with about $10^{3}$ atoms and width $\approx 2\xi \approx 4 \mu$m (so that $\nu = 0.5$) and a linear trap with Gaussian shape, normalized amplitude 0.5 and width $\approx \xi \approx 2 \mu$m (so that $x_c = 0.5$). The theoretical prediction is that such a soliton is trapped if its velocity is below $0.55c$ (because $\mu_{\text{crit}} \simeq 0.14$, see Figure 3). However, in this experiment, we can consider variations of the external magnetic field $B$ around the value $352$ G, where the scattering length has the minimal value $\approx -0.23$ nm. Increasing the field to the value $B = 450$ G we can increase the scattering length to the value $\approx -0.18$ nm. This means that the scattering length can be varied by $25\%$, and thus a nonlinear barrier $V_{nl}$ with normalized amplitude 0.5 can be generated. The theoretical prediction is that, in the presence of the linear trap and the nonlinear barrier, the soliton will be trapped only if its velocity is below $0.2c$ (because $\mu_{\text{crit}} \approx 0.05$, see Figure 4), and it will be transmitted otherwise. This means that the nonlinear modulation dramatically enhances the domain of parameters for which solitons can be transmitted through the linear trap.

V. CONCLUSION

In this paper we have investigated the time-dependent nonlinear scattering of bright solitonic matter waves through different types of barriers. We have considered the transmission of matter waves through inhomogeneities in the form of localized linear and nonlinear potentials. The adiabatic dynamics of the wavepackets as well as the radiative processes during the transmission have been analyzed.

To analyze the dynamics we use the perturbed IST theory, which allows us to predict the trapping of a bright soliton by a trap potential and the reflection of a soliton by a barrier potential. The parameters (mass and velocity) of the transmitted soliton can be estimated by computing the radiated mass and energy and by using the conservations of the total mass and energy. The enhanced transmission of a soliton through a linear trap by a nonlinear modulation of the scattering length is explained by this theory.

The analytical predictions have been checked by comparisons with numerical simulations of the GP equation. The formulas are valid in the asymptotic framework where the potentials have small amplitudes. It turns out that, for small or moderate potential amplitudes $|V_{0}| \leq 0.5$, $|V_{nl}| \leq 0.5$, the perturbed IST theory gives quantitatively accurate predictions. For large potential amplitudes $|V_{0}| \geq 1$, $|V_{nl}| \geq 1$, the theoretical predictions of the perturbed IST theory are still in qualitative agreement with the numerical results. This means that the perturbed IST theory is useful for probing the parameter space and exhibiting interesting phenomena. The enhanced transmission can be observed in the experiments with bright matter wave solitons in elongated trap with proper variation in space of the external magnetic field and the trap potential [17, 18]. One of the problems that should be addressed for future consideration by this approach is the nonlinear resonant scattering on the (periodic or random) chain of nonlinear barriers [19] and the scattering on time-dependent linear and nonlinear barriers [20]. The latter problem is important for many areas of condensed matter.
