Received: date / Accepted: date

Abstract Over the last four years, methods based on Deep Convolutional Neural Networks (DCNNs) have shown impressive performance improvements for object detection and recognition problems. This has been made possible due to the availability of large annotated datasets, a better understanding of the non-linear mapping between input images and class labels as well as the affordability of GPUs. In this paper, we present the design details of a deep learning system for end-to-end unconstrained face verification/recognition. The quantitative performance evaluation is conducted using the newly released IARPA Janus Benchmark A (IJB-A), the JANUS Challenge Set 2 (JANUS CS2), and the LFW dataset. The IJB-A dataset includes real-world unconstrained faces of 500 subjects with significant pose and illumination variations which are much harder than the Labeled Faces in the Wild (LFW) and Youtube Face (YTF) datasets. JANUS CS2 is the extended version of IJB-A which contains not only all the images/frames of IJB-A but also includes the original videos for evaluating video-based face verification system. Some open issues regarding DCNNs for object recognition problems are then discussed.

1 Introduction

Face verification is one of the core problems in computer vision and has been actively researched for over two decades [87]. In face verification, given two videos or images, the objective is to determine whether they belong to the same person. Many algorithms have been shown to work well on images that are collected in controlled settings. However, the performance of these algorithms often degrades significantly on images that have large variations in pose, illumination, expression, aging, and occlusion. In addition, for an end-to-end automated face verification system to be effective, it also needs to handle errors that are introduced by algorithms for automatic face detection, face association, and facial landmark detection.

Existing methods have focused on learning robust and discriminative representations from face images and videos. One approach is to extract an over-complete and high-dimensional feature representation followed by a learned metric to project the feature vector into a low-dimensional space and to compute the similarity scores. For example, high-dimensional multi-scale local binary pattern (LBP) [14] features extracted from local patches around facial landmarks and Fisher vector (FV) [65][16] features have been shown to be effective for face recognition. Despite significant progress, the performance of these systems has not been adequate for deployment. However, given the availability of millions of annotated data, GPUs and a better understanding of the nonlinearities, DCNNs are providing much better performance on tasks such as object recognition [43][70], object/face detection [31][55], face verification/recognition [33][53]. It has been shown that DCNN models can not only characterize large data variations but also learn a compact and discriminative rep-
representation when the size of the training data is sufficiently large. In addition, it can be generalized to other vision tasks by fine-tuning the pre-trained model on the new task [27].

In this paper, we present an end-to-end automated face verification system. Due to the robustness of DCNNs, we build each component of our system based on separate DCNN models. The face detection and face alignment modules (i.e., face detection and facial landmark detection modules) use the DCNN architecture proposed in [13] to perform better than many off-the-shelf software systems for the IJB-A dataset. For face verification, we train two DCNN models trained using the CASIA-WebFace [83] dataset. Finally, we compare the performance of our approach with many face matchers on the IJB-A dataset which are being carried out or have been recently completed [1]. The proposed system is fully automatic and yields comparable or better performance than other existing algorithms when evaluated on IJB-A and CS2 datasets. Although the IJB-A dataset contains significant variations in pose, illumination, expression, resolution and occlusion which are much harder than the Labeled Faces in the Wild (LFW) datasets, we present verification results for the LFW dataset too.

The rest of the paper is organized as follows. We briefly review closely related works in Section 2. In Section 3, we present the design details of a deep learning system for end-to-end unconstrained face verification and recognition, including face detection, face association, face alignment, and face verification. Experimental results using IJB-A, CS2, and LFW datasets are presented in Section 4. Some open issues regarding the use of DCNNs for object/face recognition problems are discussed in Section 5. Finally, we conclude the paper in Section 6 with a brief summary and discussion.

2 Related Work

A typical end-to-end face verification system consists of the following components: (1) face detection and (2) face association to localize faces, (3) facial landmark detection to align faces, and (4) face verification to verify a subject’s identity. Due to the large number of published papers in the literature, we briefly review only some relevant works for each component.

2.1 Face Detection

The face detection method introduced by Viola and Jones [74] is based on cascaded classifiers built using the Haar wavelet features. Zhu et al. [90] improved the performance of face detection algorithm using the deformable part model (DPM) approach, which treats each facial landmark as a part and uses the HOG features to simultaneously perform face detection, pose estimation, and landmark localization. However, the key challenge in unconstrained face detection is that features like Haar wavelets and HOG do not capture the salient facial information at different poses and illumination conditions. It has been shown in [27] that a deep CNN pre-trained with the Imagenet dataset can be used as a meaningful feature extractor for various vision tasks. The method based on Regions with CNN (R-CNN) [58] computes region-based deep features and attains state-of-art face detection performance. In addition, since the deep pyramid [32] removes the fixed-scale input dependency in deep CNNs, it is attractive to be integrated with the DPM approach to further improve the detection accuracy across scale [55].

2.2 Facial Landmark Detection

Facial landmark detection is an important component for a face verification system to align the faces into canonical coordinates and to improve the performance of verification algorithms. Pioneering works such as Active Appearance Models (AAM) [20] and Active Shape Models (ASM) [21] are built using the PCA constraints on appearance and shape. In [22], Cristinacce et al. generalized the ASM model to a Constrained Local Model (CLM), in which every landmark has a shape constrained descriptor to capture the appearance. Zhu et al. [90] used a part-based model for face detection, pose estimation and landmark localization assuming the face shape to be a tree structure. Asthana et al. [6] combined the discriminative response map fitting with CLM. In general, these methods learn a model that directly maps the image appearance to the target output. Nevertheless, the performance of these methods depends on the robustness of local descriptors. In [43], the deep features are shown to be robust to different challenging variations. Sun et al. [68] proposed a cascade of carefully designed CNNs, in which at each level, outputs of multiple networks are fused for landmark estimation and achieve good performance. Unlike [68], we use a single CNN, carefully designed to provide a unique key-point descriptor and achieve better performance.
2.3 Face Association

The video-based face verification system \cite{17} requires consistently-tracked faces to capture the diverse pose and spatial-temporal information for analysis. In addition, there is usually more than one person shown in the videos, and thus multiple face images from different individuals should be correctly associated between video frames. Several recent techniques achieve multiple object tracking by modeling the motion context \cite{84}, track management \cite{29}, and guided tracking using the confidence map of the detector \cite{9}. Multi-object tracking methods based on tracklet linking \cite{38,59,7} usually rely on the Hungarian algorithm \cite{4} to optimally assign the detected bounding boxes to existing tracklets. Roth et al. \cite{59} adapted the framework of multi-object tracking methods based on tracklet linking approach to track multiple faces; Several face-specific metrics and constraints have been introduced to enhance the reliability of face tracking. A recent study \cite{19} proposed to manage the tracks generated by a continuous face detector without relying on long-term observations. In unconstrained scenarios, the camera can be affected by abrupt movements, which makes consistent tracking challenging. Du et al. proposed a conditional random field (CRF) framework for face association in two consecutive frames by utilizing the affinity of facial features, location, motion, and clothing appearance \cite{28}. 

2.4 Feature Representation for Face Recognition

Learning invariant and discriminative feature representations is the first step in a face verification system. Ahonen et al. \cite{8} showed that the Local Binary Pattern (LBP) is effective for face recognition. Chen et al. \cite{14} demonstrated good results for face verification using the high-dimensional multi-scale LBP features extracted from patches around facial landmarks. However, recent advances in deep learning methods have shown that compact and discriminative representations can be learned using a DCNN trained using very large datasets. Taigman et al. \cite{72} learned a DCNN model on the frontalized faces generated with a general 3D shape model from a large-scale face dataset and achieved better performance than many traditional methods. Sun et al. \cite{63} achieved results that surpass human performance for face verification on the LFW dataset using an ensemble of 25 simple DCNN with fewer layers trained on weakly aligned face images from a much smaller dataset than \cite{72}. Schroff et al. \cite{65} adapted the state-of-the-art deep architecture in object recognition to face recognition and trained using a large-scale unaligned private face dataset with the triplet loss. Parkhi et al. \cite{64} trained a very deep convolutional network based on VGGNet for face verification and demonstrated impressive results. These studies essentially demonstrate the effectiveness of the DCNN model for feature learning and detection/recognition/verification problems.
2.5 Metric Learning

Learning a similarity measure from data is the other key component for improving the performance of a face verification system. Many approaches have been proposed in the literature that essentially exploit the label information from face images or face pairs. For instance, Weinberger et al. [70] proposed the Large Margin Nearest Neighbor (LMNN) metric which enforces the large margin constraint among all triplets of labeled training data. Taigman et al. [71] learned the Mahalanobis distance using the Information Theoretic Metric Learning (ITML) method [25]. Chen et al. [13] proposed a joint Bayesian approach for face verification which models the joint distribution of a pair of face images and uses the ratio of between-class and within-class probabilities as the similarity measure. Hu et al. [37] learned a discriminative metric within the deep neural network framework. Schröff et al. [63] and Parkhi et al. [54] optimized the DCNN parameters based on the triplet loss which directly embeds the DCNN features into a discriminative subspace and presented promising results for face verification.

3 Proposed System

The proposed system is a complete pipeline for performing automatic face verification. We first perform face detection to localize faces in each image and video frame. Then, we associate the detected faces with the common identity across the videos and align the faces into canonical coordinates using the detected landmarks. Finally, we perform face verification to compute the similarity between a pair of images/videos. The system is illustrated in Figure 1. The details of each component are presented in the following sections.

3.1 Face Detection

All the faces in the images/video frames are detected using a DCNN-based face detector, called the Deep Pyramid Deformable Parts Model for Face Detection (DP2MFD) [55], which consists of two modules. The first module generates a seven level normalized deep face pyramid for any input image of arbitrary size, as illustrated in the first part of Figure 1. The same CNN architecture as Alexnet [43] is adopted for extracting the deep features. This image pyramid network generates a pyramid of 256 feature maps at the fifth convolution layer (conv5). A $3 \times 3$ max filter is applied to the feature pyramid at a stride of one to obtain the $\text{max}_5$ layer. Typically, the activation magnitude for a face region decreases with the size of the pyramid level. As a result, a large face detected by a fixed-size sliding window at a lower pyramid level will have a high detection score compared to a small face getting detected at a higher pyramid level. In order to reduce this bias to face size, we apply a z-score normalization step on the $\text{max}_5$ features at each level. For a 256-dimensional feature vector $x_{i,j,k}$ at the pyramid level $i$ and location $(j,k)$, the normalized feature $\tilde{x}_{i,j,k}$ is computed as:

$$\tilde{x}_{i,j,k} = \frac{x_{i,j,k} - \mu_i}{\sigma_i},$$

where $\mu_i$ is the mean feature vector, and $\sigma_i$ is the standard deviation for the pyramid level $i$. We refer to the normalized $\text{max}_5$ features as $\text{norm}_5$. Then, the fixed-length features from each location in the pyramid are extracted using the sliding window approach.

The second module is a linear SVM, which takes these features as input to classify each location as face or non-face, based on their scores. A root-only DPM is trained on the $\text{norm}_5$ feature pyramid using a linear SVM. In addition, the deep pyramid features are robust to not only pose and illumination variations but also to different scales. The DP2MFD algorithm works well in unconstrained settings as shown in Figure 2. We also present the face detection performance results under the face detection protocol of the IJB-A dataset in Section 4.

3.2 Facial Landmark Detection

Once the faces are detected, we perform facial landmark detection for face alignment. The proposed facial landmark detection algorithm [35] works in two stages. We model the task as a regression problem, where beginning with the initial mean shape, the target shape is reached through regression. The first step is to perform feature extraction of a patch around a point of the shape followed by linear regression as described in [57][12]. Given a face image $I$ and the initial shape $S^0$, the regressor computes the shape increment $\Delta S$ from the deep descriptors and updates the face shape using

$$S^t = S^{t-1} + W^t\Phi(I, S^{t-1})$$

The CNN features (represented as $\Phi$ in 2) carefully designed with the proper number of strides and pooling, are used as the features to perform regression. We use the same CNN architecture as Alexnet [43] with the pretrained weights for the ImageNet dataset as shown in Figure 3. In addition, we finetune the CNN with the
face detection task. This helps the network to learn features specific to faces. Furthermore, we adopt the cascade regression, in which the output generated by the first stage is used as an input for the next stage. The number of stages has been fixed at 5 in our system. The patches selected for feature extraction are reduced subsequently in later stages to improve the localization of facial landmarks. After the facial landmark detection is completed, each face is aligned into the canonical coordinate using the similarity transform and seven landmark points (i.e., two left eye corners, two right eye corners, nose tip, and two mouth corners).

3.3 Face Association

Because there are multiple subjects appearing in the frames of each video of the IJB-A dataset, performing face association to assign each face to its corresponding subject is an important step for us to pick the correct subject for face verification. Thus, once the faces in the images and video frames are detected, we track multiple faces by integrating results from the face detector, face tracker, and a tracklet linking step. The second part of Figure 1 shows the block diagram of the multiple face tracking system. We apply the face detection algorithm in every fifth frame using the face detection method presented in Section 3.1. The detected bounding box is considered as a novel detection if it does not have an overlap ratio with any bounding box in the previous frames larger than $\gamma$. The overlap ratio of a detected bounding box $b_d$ and a bounding box $b_{tr}$ in the previous frames is defined as

$$s(b_d, b_{tr}) = \frac{area(b_d \cap b_{tr})}{area(b_{tr})}. \tag{3}$$

We empirically set the overlap threshold $\gamma$ to 0.2. A face tracker is created from a detection bounding box that is treated as a novel detection. For face tracking, we use the Kanade-Lucas-Tomasi (KLT) feature tracker [64] to track the faces between two consecutive frames. To avoid the potential drift of trackers, we update the bounding boxes of the tracker by those provided by the face detector in every fifth frame. The detection bounding box $b_d$ replaces the tracking bounding boxes $b_{tr}$ of a tracklet in the previous frame if $s(b_d, b_{tr}) \leq \gamma$. A face tracker is terminated if there is no corresponding face detection overlapping with it for more than $t$ frames. We set $t$ to 4 based on empirical grounds.

In order to handle the fragmented face tracks resulting from occlusions or unreliable face detection, we use the tracklet linking method proposed by [7] to associate the bounding boxes in the current frames with tracklets in the previous frames. The tracklet linking method consists of two stages. The first stage is to associate the bounding boxes provided by the tracker or the detector in the current frame with the existing tracklet in previous frames. This stage consists of local and global associations. The local association step associates the bounding boxes with the set of tracklets, having high confidence. The global step associates the remaining bounding boxes with the set of tracklets of low confidence. The second stage is to update the confidence of the tracklets, which will be used for determining the tracklets for local or global association in the first stage. We show sample face association results for some videos from the CS2 dataset in Figure 4.
3.4 Deep Convolutional Face Representation

In this work, we train two deep convolutional networks. One is trained using tight face bounding boxes (DCNNS), and the other using large bounding boxes which include more contexts (DCNNL) information. In Section 4, we present results which show that both networks can capture discriminative information and complement each other. In addition, the fusion of two networks does significantly improve the final performance. The architectures of both networks are summarized in Tables 1 and 2.

Stacking small filters to approximate large filters and building very deep convolutional networks reduces the number of parameters but also increases the non-linearity of the network in [66][70]. In addition, the resulting feature representation is compact and discriminative. Therefore, for (DCNNS), we use the same network architecture presented in [15] and train it using the CASIA-WebFace dataset [83]. The dimensionality of the input layer is 100 × 100 × 3 for RGB images. The network includes 10 convolutional layers, 5 pooling layers, and 1 fully connected layer. Each convolutional layer is followed by a parametric rectified linear unit (PReLU) [36], except the last one, conv52. Moreover, two local normalization layers are added after conv12 and conv22, respectively, to mitigate the effect of illumination variations. The kernel size of all filters is 3 × 3. The first four pooling layers use the max operator, and pool5 uses average pooling. The feature dimensionality of pool5 is thus equal to the number of channels of conv52 which is 320. The dropout ratio is set as 0.4 to regularize Fc6 due to the large number of parameters (i.e. 320 × 1054). The pool5 feature is used for face representation. The extracted features are further L2-normalized to unit length before the metric learning stage. If there are multiple images and frames available for the subject template, we use the average of the pool5 features as the overall feature representation.

On the other hand, for the DCNNL, the deep network architecture closely follows the architecture of the AlexNet [14] with some notable differences: reduced number of parameters in the fully connected layers; use of Parametric Rectifier Linear units (PReLU’s) instead of ReLU, since they allow a negative value for the output based on a learnt threshold and have been shown to improve the convergence rate [36]. The reason for using the AlexNet architecture in the convolutional layers is due to the fact that we initialize the convolutional layer weights with weights from the AlexNet model which was trained using the ImageNet challenge dataset. Several recent works [83], [50] have empirically shown that this transfer of knowledge across different networks, albeit for a different objective, improves performance and more significantly reduces the need to train using a large number of iterations. To learn more domain specific information, we add an addi-

Fig. 4 Sample results of our face association method for videos of JANUS CS2 which is the extension dataset of IJB-A.
3.5 Triplet Similarity Embedding

To further improve the performance of our deep features, we obtain a low-dimensional discriminative projection of the deep features, called the Triplet Similarity Embedding (TSE) that is learnt using the training data provided for each split of IJB-A. The output of the procedure is an embedding matrix $\mathbf{W} \in \mathbb{R}^{n \times M}$ where $M$ is the dimensionality of the deep descriptor (320 for DCNN$_S$ and 512 for DCNN$_E$) and we set $n = 128$, thus achieving dimensionality reduction in addition to an improvement in performance.

The objective of this method is to push similar pairs together and dissimilar pairs apart in the low-dimensional space. For learning $\mathbf{W}$, we solve an optimization problem based on constraints involving triplets - each containing two similar samples and one dissimilar sample. Consider a triplet $\{a, p, n\}$, where $a$ (anchor) and $p$ (positive) are from the same class, but $n$ (negative) belongs to a different class. Our objective is to learn a linear projection $\mathbf{W}$ from the data such that the following constraint is satisfied:

$$(\mathbf{W}a)^T \cdot (\mathbf{W}p) > (\mathbf{W}a)^T \cdot (\mathbf{W}n)$$

(4)

In our case, $\{a, p, n\} \in \mathbb{R}^M$ are deep descriptors which are normalized to unit length. As such, $(\mathbf{W}a)^T \cdot (\mathbf{W}p)$ is the dot-product or the similarity between $a, p$ under the projection $\mathbf{W}$. The constraint in (4) requires that the similarity between the anchor and positive samples should be higher than the similarity between the anchor and negative samples in the low dimensional space represented by $\mathbf{W}$. Thus, the mapping matrix $\mathbf{W}$ pushes similar pairs closer and dissimilar pairs apart, with respect to the anchor point. By choosing the dimensionality of $\mathbf{W}$ as $n \times M$ where $n < M$, we achieve dimensionality reduction in addition to better performance. For our work, we fix $n = 128$ based on cross validation.

Given a set of labeled data points, we solve the following optimization problem:

$$\arg\min_{\mathbf{W}} \sum_{a, p, n \in \mathcal{T}} \max(0, \alpha + a^T \mathbf{W}^T \mathbf{W} n - a^T \mathbf{W}^T \mathbf{W} p)$$

(5)

where $\mathcal{T}$ is the set of triplets and $\alpha$ is a margin parameter chosen based on the validation set. In practice, the above problem is solved in a Large-Margin framework using Stochastic Gradient Descent (SGD) and the triplets are sampled online. The update step for solving (5) with SGD is:
\[ W_{t+1} = W_t - \eta \cdot W_t \cdot (a(n-p)^T + (n-p)a^T) \]  
where \( W_t \) is the estimate at iteration \( t \), \( W_{t+1} \) is the updated estimate, \( \{a, p, n\} \) is the triplet sampled at the current iteration and \( \eta \) is the learning rate which is set to 0.01 for the current work.

The entire procedure takes 3-5 minutes per split using a standard C++ implementation. More details regarding the optimization algorithm can be found in [62]. At each iteration, we sample 1000 instances from the whole training set to choose the negatives. Since the training set is relatively small for the datasets considered in this experiment, the entire training set is held in memory. Going forward this could be made efficient by using a buffer which will be replenished periodically, thus requiring a constant memory requirement. The computational complexity of each iteration is \( O(M^2) \), that is, the complexity varies quadratically with the dimension of the deep descriptor. The technique closest to the one presented in this section, which is used in recent works ([54], [63]) computes the embedding \( W \) based on satisfying the distance constraints given below:

\[
\arg\min_W \sum_{a,p,n \in T} \max\{0, a + (a - p)^T W^T W (a - p) - \}
\]

\[
(a - n)^T W^T W (a - n) \}
\]

To be consistent with the terminology used in this paper, we call it Triplet Distance Embedding (TDE). It should be noted that the TSE formulation is different from TDE, in that, the current work uses inner-product based constraints between triplets to optimize for the embedding matrix as opposed to norm-based constraints used in the TDE method.

4 Experimental Results

In this section, we present the results of the proposed automatic system for both face detection and face verification tasks on the challenging IARPA Janus Benchmark A (IJB-A) [42], its extended version Janus Challenging set 2 (JANUS CS2) dataset, and the LFW dataset. The JANUS CS2 dataset contains not only the sampled frames and images in the IJB-A, but also the original videos. In addition, the JANUS CS2 dataset includes considerably more test data for identification and verification problems in the defined protocols than the IJB-A dataset. The receiver operating characteristic curves (ROC) and the cumulative match characteristic (CMC) scores are used to evaluate the performance of different algorithms for face verification. The ROC curve measures the performance in the verification scenarios, and the CMC score measures the accuracy in a closed set identification scenarios.

4.1 Face Detection on IJB-A

The IJB-A dataset contains images and sampled video frames from 500 subjects collected from online media [12], [18]. For the face detection task, there are 67,183 faces of which 13,741 are from images and the remaining are from videos. The locations of all faces in the IJB-A dataset have been manually annotated. The subjects were captured so that the dataset contains wide geographic distribution. Nine different face detection algorithms were evaluated on the IJB-A dataset [18], and the algorithms compared in [18] include one commercial off the shelf (COTS) algorithm, three government off the shelf (GOTS) algorithms, two open source face detection algorithms (OpenCV’s Viola Jones and the detector provided in the Dlib library), and GOTS ver 4 and 5. In Figure 7, we show the precision-recall (PR) curves and the ROC curves, respectively corresponding to the method used in our work and one of the best reported methods in [18]. From the results, we see that the face detection algorithm used in our system outperforms the best performing method reported in [18] by a large margin. In Figure 5 (b), we illustrate typical faces in the IJB-A dataset that are not detected by DP2MFD, and we can find the faces to be usually in very extreme conditions which contain limited information for face verification. However, in Figure 8 (a), we also show that the DP2MFD algorithm can handle very difficult faces but relatively reasonable as compared to those in 8 (b). As shown in Figure 6, our DP2MFD algorithm also achieves top performance in the challenging FDDB benchmark [40] for face detection with a large performance margin compared to most algorithms. Some of the recent published methods compared in the FDDB evaluation include Faceness [52], HeadHunter [53], JointCascade [24], CCF [50], SquaresChanFtrs-5 [53], CascadeCNN [48], Structured Models [79], DDFFD [30], NDPPFace [49], PEP-Adapt [47] and TSM [89]. More comparison results with other face detection data sets are available in [53]. Since the CS2 dataset has not been released to public, we are not able to provide comparisons with other existing face detectors.
4.2 Facial Landmark Detection on IJB-A

We also evaluate the performance of our facial landmark detection method on the IJB-A dataset. For the training data, we take 3148 images in total from the LFPW [8], Helen [46] and AFW [89] datasets and test on IJBA-A dataset. The subjects were captured so that the dataset contains wide geographic distribution. The challenge comes through the wide diversity in pose, illumination and resolution. Our method produce 68 facial landmark points following MultiPIE [34] markup format. We evaluate the performance using the Normalized Mean Square Error and average pt-pt error (normalized by face size) vs fraction of images plots of different methods. Since IJB-A is annotated only with 3 key-points on the faces (two eyes and nose base) by human annotators, the interocular distance error was normalized by the distance between nose tip and the midpoint of the eye centers. In Figure 9, we present the comparison of our algorithm with [89], [5] and [41]. For the Helen dataset, we show the performance of 49-point and full 68-point results in Table 3. Our deep descriptor-based global shape regression method outperforms the above mentioned state-of-the-art methods in both high-quality (Helen) and low-quality (IJB-A) images. Sample detected landmarks results are shown in Figure 10. More evaluation results for landmark detection on other standard data sets may be found [45].

Once the facial landmark detection is completed, we choose seven landmark points (i.e. two left eye corners,
two right eye corners, nose tip, and two mouth corners) out of the detected 68 points and apply the similarity transform to warp the faces into the canonical coordinate.

| Method       | 68 pts | 49 pts |
|--------------|--------|--------|
| Zhu et al. [29] | 8.16   | 7.43   |
| DRMF [1]     | 6.70   | -      |
| RCPR [11]    | 5.93   | 4.64   |
| SDM [78]     | 5.50   | 4.25   |
| GN-DPM [23]  | 5.69   | 4.06   |
| CFAN [86]    | 5.33   | -      |
| CFSS [88]    | 4.63   | 3.47   |
| LDDR         | 4.76   | 2.36   |

4.3 IJB-A and JANUS CS2 for Face Verification

For the face verification task, both IJB-A and JANUS CS2 datasets contain 500 subjects with 5,397 images and 2,042 videos split into 20,412 frames, 11.4 images and 4.2 videos per subject. Sample images and video frames from the datasets are shown in Figure 11 (i.e., the videos are only released for the JANUS CS2 dataset.) The IJB-A evaluation protocol consists of verification (1:1 matching) over 10 splits. Each split contains around 11,748 pairs of templates (1,756 positive and 9,992 negative pairs) on average. Similarly, the identification (1:N search) protocol also consists of 10 splits, which are used to evaluate the search performance. In each search split, there are about 112 gallery templates and 1,763 probe templates (i.e., 1,187 genuine probe templates and 576 impostor probe templates). On the other hand, for the JANUS CS2, there are about 167 gallery templates and 1,763 probe templates and all of them are used for both identification and verification. The training set for both datasets contains 333 subjects, and the test set contains 167 subjects without any overlapping subjects. Ten random splits of training and testing are provided by each benchmark, respectively. The main differences between the IJB-A and JANUS CS2 evaluation protocols are that (1) IJB-A considers the open-set identification problem and the JANUS CS2 considers the closed-set identification and (2) IJB-A considers the more difficult pairs which are the subsets from the JANUS CS2 dataset.

Unlike the LFW and YTF datasets, which only use a sparse set of negative pairs to evaluate the verification performance, the IJB-A and JANUS CS2 both divide the images/video frames into gallery and probe sets so that all the available positive and negative pairs are used for the evaluation. Also, each gallery and probe set consist of multiple templates. Each template contains a combination of images or frames sampled from multiple image sets or videos of a subject. For example, the size of the similarity matrix for JANUS CS2 split1 is $167 \times 1806$ where 167 are for the gallery set and 1806 for the probe set (i.e. the same subject reappears multiple times in different probe templates). Moreover, some templates contain only one profile face with a challenging pose with low quality imagery. In contrast to the LFW and YTF datasets, which only include faces detected by the Viola Jones face detector [74], the images in the IJB-A and JANUS CS2 contain extreme pose, illumination, and expression variations. These factors essentially make the IJB-A and JANUS CS2 challenging face recognition datasets [42].
Fig. 11 Sample images and frames from the IJB-A (top) and JANUS CS2 datasets (bottom). Challenging variations due to pose, illumination, resolution, occlusion, and image quality are present in these images.

Fig. 12 The performance evaluation for face verification tasks of (a) DCNN$_S$ and (b) DCNN$_L$ of before finetuning, with finetuning, and with finetuning and triplet similarity embedding for the JANUS CS2 dataset under Setup 3 (semi-automatic mode). Fine tuning is done only using the training data in each split.

Fig. 13 (a) and (b) show the face verification performance of the fusion model for JANUS CS2 and IJB-A (1:1) verification, respectively, and (c) shows the face identification performance of the fusion model for IJB-A (1:N) identification for all the three setups. Fine tuning is done only using the training data in each split.

4.4 Performance Evaluations of Face Verification on IJB-A and JANUS CS2

Since the system works end-to-end, we have considered two modes of evaluations, automatic and semi-automatic modes. This enables the handling of cases where we are unable to detect any of the faces in the images of the given template and also to compare the performance with the one using the metadata provided with the dataset. We describe the setups of performance evaluation in details as follows:

- **Setup 1 (manual mode):** Under this setup, we directly use the three facial landmarks and face bounding boxes provided along with the datasets.
- **Setup 2 (automatic mode):** In this setup when we get a video we use the face association method to detect and track the faces and to extract the bounding box to perform fiducial detection. If it is an im-
age, we perform detection and facial landmark detection independently. If for every image or frame in a template in which we are unable to detect the target person, we are unable to compare the template with others and thus assign all the corresponding entries for the template in the similarity matrices to the lowest similarity scores, -Inf.

- **Setup 3 (semi-automatic mode):** In this setup if we are able to detect the target person in an image then we follow setup 2. Otherwise, we follow setup 1 to use the metadata of the dataset for the faces which are not detected and tracked by our algorithms.

First, we present the ROC curves of DCNN_S and DCNN_L of the Setup 3 (i.e., semi-automatic mode) for the JANUS CS2 dataset in Figure 12. From the figures, both networks consistently improve the results after finetuning the models which are trained originally with the CASIA-WebFace dataset on the training data of JANUS CS2. Triplet similarity embedding (TSE) further increase the performance for both networks, especially for the TAR number at the low FAR interval. For all the results presented here, fine tuning is done using only the training data in each split. The gallery dataset is not used for parameter fine tuning or for triplet similarity embedding. Then, we perform the fusion of the two networks by adding the corresponding similarity scores together and demonstrate the fusion results of all the three setup for the verification task of both JANUS CS2 and IJB-A in Figure 13 (a) and (b), respectively. In Figure 13 (c), we present the CMC curve for the IJB-A identification task. From Figure 13 it can be seen that even the simple fusion strategy used in this work significantly boosts the performance. Since DCNN_S is trained using tight face bounding boxes (DCNN_S) and DCNN_L using the large ones which includes more contexts (DCNN_L), one possible reason for the performance improvement is that the two networks contain discriminative information learned from different scales and complement each other. In addition, the figure also shows that the performance of our system in Setup 2 (the automatic mode) is comparable to Setup 1 (the manual mode) and Setup 3 (the semi-automatic mode). This demonstrates the robustness of each component of our system.

Besides using the average feature representation, we also perform media averaging which is to first average the features coming the same media (image or video) and then further average the media average features to generate the final feature representation. We show the results before and after media averaging for both IJB-A and JANUS CS2 dataset in Table 4 and in Table 5. It is clear that media averaging significantly improves the performance.

Tables 6 and 7 summarize the scores (i.e., both ROC and CMC numbers) produced by different face verification methods on the IJB-A and JANUS CS2 datasets, respectively. For the IJB-A dataset, we compare our fusion results (i.e., we perform finetuning and TSE in Setup 3) with DCNN_3d (bilinear CNN [60]), DCNN_pose (multi-pose DCNN models [2]), [81], DCNN_3d [52], template adaptation (TP) [29], DCNN_face [41] and the ones reported recently by NIST where JanusB-092015 achieved the best verification results, and JanusD-071715 the best identification results. For the JANUS CS2 dataset, Table 7 includes, a DCNN-based method [75], Fisher vector-based method [64], DCNN_pose [2], DCNN_3d [52], and two commercial off-the-shelf matchers, COTS and GOTS [42]. From the ROC and CMC scores, we see that the fusion of DCNN methods significantly improve the performance. This can be attributed to the fact that the DCNN model does capture face variations over a large dataset and generalizes well to a new small dataset.

In addition, the performance results of Janus B (JanusB-092015), Janus D (JanusD-071715), DCNN_3d and DCNN_pose systems have produced results for setup 1 (based on landmarks provided along with the dataset) only.

4.5 Labeled Face in the Wild

We also evaluate our approach on the well-known LFW dataset [39] using the standard protocol which defines 3,000 positive pairs and 3,000 negative pairs in total and further splits them into 10 disjoint subsets for cross validation. Each subset contains 300 positive and 300 negative pairs. It contains 7,701 images of 4,281 subjects. We compare the mean accuracy of the proposed deep model with other state-of-the-art deep learning-based methods: DeepFace [72], DeepID2 [69], DeepID3 [67], FaceNet [63], Yi et al. [63], Wang et al. [71], Ding et al. [29], Parkhi et al. [51], and human performance on the “funneled” LFW images. The results are summarized in Table 8. It can be seen that our approach performs comparable to other deep learning-based methods. Note that some of the deep learning-based methods compared in Table 8 use millions of data samples for training the model. In comparison, we use only the CASIA dataset for training our model which has less than 500K images.
### Table 4 Results on the IJB-A dataset. The TAR of all the approaches at FAR=0.1 and 0.01 for the ROC curves (IJB-A 1:N identification). We also show the results before and after media averaging where m means media averaging.

4.6 Comparison with Methods based on Annotated Metadata

Most systems compared in this paper produced the results for setup 1 which is based on landmarks provided along with the dataset only (i.e., except DCNN_{pdx}). For DCNN_{pdx} [52], the number of the face images is augmented along with the original CASIA-WebFace dataset by around 2 million using 3D morphable models. On the other hand, NANN [51] and TP [23] used datasets with more than 2 million face images to train the model. However, the networks used in this work were trained with the original CASIA-WebFace which contains around 500K images. In addition, TP adapted the one-shot similarity framework [77] with linear support vector machine for set-based face verification and trained the metric on-the-fly with the help of a pre-selected negative set during testing. Although TP achieved significantly better results than other approaches, it takes more time during testing than the proposed method since our metric is trained off-line and requires much less time for testing than TP. We expect the performance of the proposed approach can also be improved by using the one-shot similarity framework. As shown in Table 6, the proposed approach achieves comparable results to other methods and strikes a balance between testing time and performance. In a recent work, DCNN_{pdx} [51], adopted a probabilistic embedding for
similarly computation and a new face preprocessing module, hyperface [56], for improved face detection and fiducials where [56] is a multi-task deep network trained for the tasks of gender classification, fiducial detection, pose estimation and face detection. We plan to incorporate hyperface into the current framework which may yield some improvement in performance.

### 4.7 Run Time

The DCNNS model for face verification is trained on the CASIA-Webface dataset from scratch for about 4 days and DCNNL, it takes 20 hours to train on the same face dataset which is initialized using the weights of Alexnet pretrained on the ImageNet dataset. The two networks are trained using NVidia Titan X with cudnn v4. The running time for face detection is around 0.7 second per image. The facial landmark detection and feature extraction steps take about 1 second and 0.006 second per face, respectively. The face association module for a video takes around 5 fps on average.

### 5 Open Issues

Given sufficient number of annotated data and GPUs, DCNNs have been shown to yield impressive performance improvements. Still many issues remain to be addressed to make the DCNN-based recognition systems robust and practical. These are briefly discussed below.

- **Reliance on large training data sets:** One of the top performing networks in the MegaFace challenge needs 500 million faces of about 10 million subjects. Such large annotated training set may not be always available (e.g. expression recognition, age estimation). So networks that can perform well with reasonable-sized training data are needed.

### Table 7: Results on the JANUS CS2 dataset. The TAR of all the approaches at FAR=0.1, 0.01, and 0.001 for the ROC curves. The Rank-1, Rank-5, and Rank-10 retrieval accuracies of the CMC curves. We report average and standard deviation of the 10 splits. The performance results of DCNNpases have produced results for setup 1 only.

| Method             | #Net | Training Set | Metric | Mean Accuracy ± Std |
|--------------------|------|--------------|--------|---------------------|
| DeepFace           | 1    | 4.4 million images of 4,030 subjects, private | cosine | 99.92% ± 0.29%      |
| DeepFace           | 7    | 4.4 million images of 4,030 subjects, private | unrestricted, SVM | 97.35% ± 0.25%      |
| DeepID2            | 25   | 202,595 images of 10,117 subjects, private | unrestricted, Joint-Bayes | 95.43%      |
| DeepID3            | 50   | 202,595 images of 10,117 subjects, private | unrestricted, Joint-Bayes | 99.15% ± 0.15%      |
| FaceNet            | 1    | 260 million images of 8 million subjects, private | l2    | 99.63% ± 0.09%      |
| Yi et al.          | 1    | 494,414 images of 10,575 subjects, public | cosine | 96.13% ± 0.30%      |
| Yi et al.          | 1    | 494,414 images of 10,575 subjects, public | unrestricted, Joint-Bayes | 97.74% ± 0.31%      |
| Wang et al.        | 1    | 494,414 images of 10,575 subjects, public | cosine | 96.95% ± 1.02%      |
| Wang et al.        | 7    | 494,414 images of 10,575 subjects, public | unrestricted, Joint-Bayes | 97.52% ± 0.76%      |
| Wang et al.        | 1    | 494,414 images of 10,575 subjects, public | unrestricted, Joint-Bayes | 97.45% ± 0.99%      |
| Wang et al.        | 7    | 494,414 images of 10,575 subjects, public | unrestricted, Joint-Bayes | 98.23% ± 0.68%      |
| Ding et al.        | 8    | 471,592 images of 9,000 subjects, public | unrestricted, TDE | 99.02% ± 0.19%      |
| Parkhi et al.      | 1    | 2.6 million images of 2,622 subjects, public | N/A   | 98.95%              |
| Human, funneled    | 1    | N/A        | N/A   | 99.20%              |
| Our DCNN9 + DCNN1 | 2    | 400,356 images of 10,548 subjects, public | cosine | 98.33% ± 0.5%      |
|                  | 2    | 400,356 images of 10,548 subjects, public | unrestricted, TSE | 98.33% ± 0.7%      |

### Table 8: Accuracy of different methods on the LFW dataset.

- **Similarity computation** and a new face preprocessing module, hyperface [56], for improved face detection and fiducials where [56] is a multi-task deep network trained for the tasks of gender classification, fiducial detection, pose estimation and face detection. We plan to incorporate hyperface into the current framework which may yield some improvement in performance.

- **4.7 Run Time**

The DCNNS model for face verification is trained on the CASIA-Webface dataset from scratch for about 4 days and DCNNL, it takes 20 hours to train on the same face dataset which is initialized using the weights of Alexnet pretrained on the ImageNet dataset. The two networks are trained using NVidia Titan X with cudnn v4. The running time for face detection is around 0.7 second per image. The facial landmark detection and feature extraction steps take about 1 second and 0.006 second per face, respectively. The face association module for a video takes around 5 fps on average.

### 5 Open Issues

- **Reliance on large training data sets:** One of the top performing networks in the MegaFace challenge needs 500 million faces of about 10 million subjects. Such large annotated training set may not be always available (e.g. expression recognition, age estimation). So networks that can perform well with reasonable-sized training data are needed.
An End-to-End System for Unconstrained Face Verification with Deep Convolutional Neural Networks

- **Invariance:** While limited invariance to translation is possible with existing DCNNs, networks that can incorporate more general invariances are needed.
- **Training time:** The training time even when GPUs are used can be several tens to hundreds of hours, depending on the number of layers used and the training data size. More efficient implementations of learning algorithms, preferably implemented using CPUs are desired.
- **Number of parameters:** The number of parameters can be several tens of millions. Novel strategies that reduce the number of parameters need to be developed.
- **Handling degradations in training data:** DCNNs robust to low-resolution, blur, illumination and pose variations, occlusion, erroneous annotation, etc. are needed to handle degradations in data.
- **Domain adaptation of DCNNs:** While having large volumes of data may help with processing test data from a different distribution than that of the training data, systematic methods for adapting the deep features to test data are needed.
- **Theoretical considerations:** While DCNNs have been around for a few years, detailed theoretical understanding is just starting to develop. Methods for deciding the number of layers, neighborhoods over which max pooling operations are performed are needed.
- **Incorporating domain knowledge:** The current practice is to rely on fine tuning. For example, for the age estimation problem, one can start with one of the standard networks such as the AlexNet and fine tune it using aging data. While this may be reasonable for somewhat related problems (face recognition and facial expression recognition), such fine tuning strategies may not always be effective. Methods that can incorporate context may make the DCNNs more applicable to a wider variety of problems.
- **Memory:** Although Recurrent CNNs are on the rise, they still consume a lot of time and memory for training and deployment. Efficient DCNN algorithms are needed to handle videos and other data streams as blocks.

6 Conclusion

We presented the design and performance of our automatic face verification system, which automatically locates faces and performs verification/recognition on newly released challenging face verification datasets, IARPA Benchmark A (IJB-A) and its extended version, JANUS CS2. It was shown that our proposed DCNN-based system can not only accurately locate the faces across images and videos but also learn a robust model for face verification. Experimental results demonstrate that the performance of the proposed system on the IJB-A dataset is much better than a FV-based method and some COTS and GOTS matchers.
