Background: Yunnan is a province of China most seriously affected by plague outbreaks. From 2005 to 2016, Plague in human was sporadically reported in Yunnan. Understanding the composition of small mammals and parasitic fleas in a plague natural focus might inform plague prevention and control measures.

Objective: This study aimed to investigate the distribution and composition of small mammals and parasitic fleas in the two plague natural foci in Yunnan Province.

Methods: This study was conducted during December 2015 to October 2016, two plague natural foci included Yulong and Jianchuan were selected as study region, small mammals were captured by Dead traps in the spring, summer, autumn and winter and the parasitic fleas were collected by combing. The relevant indicator of small mammals and parasitic fleas were calculated, with compared by the Chi-square test and Fisher’s exact test.

Results: In the study, 884 small mammals representing 18 species were captured in the Yulong plague focus, at a density of 17.98%. From these mammals, 484 parasitic fleas representing 9 species were collected, with the flea prevalence of 24.77%. Further, 1069 small mammals representing 17 species were captured in the Jianchuan plague focus, at a density of 21.29%. From these mammals, 618 parasitic fleas representing 9 species were collected, with the flea prevalence of 27.60%. The small mammal density in the Jianchuan plague focus was significantly higher than that in the Yulong plague focus (Chi-squared test, \(P<0.01\)).

Conclusion: Apodemus chevrieri, Apodemus draco, and Eothenomys miletus were the dominant hosts in the two plague foci. In Yulong focus, Neopsylla specialis specialis and Ctenophthalmus (Sinocentenophthalmus) quadartus were the common dominant vectors. The compositions of small mammals and parasitic fleas in the two plague natural foci are similar; while some unique characteristics were existed in the Yulong plague focus. A. draco thrives better and E. proditor was only a secondary host or popular host. N. specialis specialis was the most abundant in summer of the Yulong plague focus, but C. (S.) quadartus was the most abundant in spring of the Jianchuan plague focus.
Introduction

Plague is caused by *Yersinia pestis* which is a gram-negative bacterium, usually transmitted by fleas bitten and small mammals as the main reservoir. Plague is one of the most serious infectious diseases in human history. To date, three plague pandemics—the Justinian Pandemic, which started in AD 541, the Black Death, which started in AD 1347, and the Third Modern Pandemic, which started in AD 1772—have caused hundreds of millions of deaths worldwide [1,2]. Plague as a natural epidemic disease, is independent of human and exists in natural foci [3]. The disease continues to be a threat to human health, with plausible outbreaks in Madagascar, sporadically spreading in Tanzania, Vietnam, China, and the United States et al in last decades [4]. According to the WHO (World Health Organization), 2,417 cases of plague and 355 cases of bubonic plague, and 209 deaths were reported in Madagascar between August 1 to November 26, 2017 [5]. This outbreak highlights the notion that plague is an active foci and continues to pose a threat to human health.

China is one of the most complex plague areas in the world, consisting of twelve types of plague natural foci. In the 21st century, the plague in Yunnan is one of the most complex plague areas in the world, consisting of twelve types of plague natural foci. In the 21st century, the plague natural foci area in Xizang (Tibet), the Yunnan Province (with Alxa League in Inner Mongolia, etc.), and Sichuan (with Sichuan Tibet and Qinghai) are relatively stable, only animal plague in the provinces remains sporadic, and animal plague areas in Inner Mongolia, Gansu, and Yunnan are still active. Therefore, previous study was mostly analyzed the characteristics of the Yulong focus from the *Y. pestis* [13]. It is still unclear whether the dominant small mammals and vector fleas are similar to the adjacent Jianchuan focus. In this study, we aim to investigate the distribution and composition of small mammals and parasitic fleas in the Yulong plague focus by comparing with those in the Jianchuan plague focus. This finding will be better understanding of the composition and distribution of small mammals and fleas may contribute to developing earlier warning methods for human plague outbreaks.

Materials and Methods

Study Design

This is a cross-sectional study based on the epidemiological information for the plague natural foci in the Yunnan province, two wild rodent plague foci included Yulong and Jianchuan were selected [8]. Small mammals were captured and parasitic fleas collected seasonally in these foci from December 2015 to October 2016.

Study Setting

The Yulong and Jianchuan plague foci are all located in the middle of the Hengduan Mountains with similar geographical environment, but separated by the low-lying valley in the center of the two regions. The Yulong plague focus is located in the northwest Yunnan province (latitude, 26°42’47”N to 26°56’13”N, longitude, 99°48’37”E to 100°16’39”E). The landscape is cultivation with alpine pine forest or mixed forest mountain area between 2900~3300 meter, having a warm temperate climate. The
Jianchuan plague focus is closing to Yulong focus (latitude, 26°10′ N to 26°45′ N, longitude 99°28′ E to 99°56′ E). The landscape is cultivation with pine forest mountain area between 2100–3000 meter, having a cold temperate climate [14]. Previously studies showed Yulong focus ever had human plagues with two people died but Jianchuan focus has long plague history only animals plagues reported [8,9,15].

**Sampling Period**

The sampling was separately conducted in each focus in each season. The four seasons are winter (which started from 30th Nov to 31th Dec, 2015), spring (6th Mar to 29th Mar, 2016), summer (7th July to 16th July, 2016), autumn (9th Oct to 18th Oct, 2016).

**Collection of Small Mammals and Parasitic Fleas**

In this study, the areas for wild trapping setting were selected and suggested by the experts from Jianchuan Station for Endemic Disease Control and Prevention of Jianchuan and Yulong CDC in different landscapes (such as woodland, cultivated, bush, etc.). They provide the setting where small mammals captured were the most or plague had occurred based on annual small mammals monitoring data and plague record data. Dead traps were used with one or two peanuts and all traps were placed the whole night started from the evening of the day to next early morning. Among them, one Dead trap were placed with no repetition in every 20 meters in per setting, this arrangement yielded at least 200 traps in one night of each focus. The captured small mammals were euthanized and brought to Jianchuan Station for Endemic Disease Control and Prevention and Yulong CDCs’ laboratory for species identification based on morphological characteristics (such as head, length of body, length of tail, hind foot, ear, fur and weight, etc.) [16]. Then, small mammals were anesthetized by ether, the parasitic fleas on their body also were anesthetized and collected using a toothbrush to comb [17]. The fleas were stored in 75% ethanol for preservation and later identification under a light microscope based on the characteristic of fleas [18].

**Statistical Analysis**

Data were encoded and digitized using the EpiData software (3.1 version) and analyzed using the R software (4.0.2 version) [19]. Information on small mammals and parasitic fleas was summarized using descriptive statistical methods. The proportion of each species of small mammals and parasitic fleas was determined as the proportion of captured individuals to the total number of captures: 
\[ P = \frac{N}{N+100} \]
where \( N \) represents the number of individuals of that species captured and \( N \) represents the total number of individuals (of all species) captured [20,21]. A proportion of more than 10% was considered to indicate “dominant” species, 1% to 10% “common” species, and less than 1% “rare” species. The following international definitions of various parasitic indicators were adopted [22,23]: fleas prevalence (%) = (total number of fleas/total number of small mammals captured) ×100, and flea index = (total number of fleas/total number of small mammals captured). Commonly used Chinese definitions were used for the capture efficiency rate and small mammal density, as follows: capture efficiency (%) = (number of collected traps/number of traps placed) ×100, small mammal density (%) = (number of small mammals captured/number of collected traps) ×100 [24].

The capture efficiency rate and flea prevalence in different focus were compared by the Chi-squared test. The compositions of small mammal species and parasitic fleas in different focus were compared by the Fisher’s exact test. The value of \( P<0.05 \) was considered to indicate statistical significance.

**Results**

In this present study, 10,120 traps were placed and 9,937 were recovered, with a capture efficiency rate of 98.20%. A total of 1953 small mammals were captured, the small mammals captured density was 19.65%. The small mammals represented 24 species, 14 genera, 6 families, and 3 orders, of which 40.86% were *Apodemus chevrieri*, 25.40% were *Eothenomys miletus*, 14.50% were *Apodemus draco*, and 2.97% were *Eothenomys proditor*. In addition, 514 small mammals were infected by fleas, the total flea prevalence was 26.32%. Overall, 1102 parasitic fleas were collected, the total flea index was 0.56. The parasitic fleas represented 11 species, 7 genera, 3 families, and 6 subfamilies, of which 30.94% were *Neopsylla specialis specialis*, 37.48% were *Ctenophthalmus (Sinocentenophthalmus) quadrates*, 6.90% were *Macrostylophora (M.) euteles*, and 5.35% were *Ctenophthalmus (Sinocentenophthalmus) yunnanensis*. The difference in capture efficiency rate between the Yulong and Jianchuan plague focus was not significant (Chi-squared test, \( P=0.1258 \)). The small mammal density in the Jianchuan plague focus was significantly higher than that in the Yulong plague focus (Chi-squared test, \( P<0.01 \)).

Table 1 showed the capture of small mammals and parasitic fleas in the Yulong and Jianchuan plague foci during the four seasons. Overall, 884 small mammals were captured and 484 parasitic fleas were collected in the Yulong plague focus, with the total flea prevalence of 24.77%, the flea prevalence and flea index were highest in winter (198, 35.75%, and 1.03 respectively) and lowest in autumn (85, 15.21%, and 0.28, respectively). By comparison, 1069 small mammals were captured and 618 parasitic fleas were collected in the Jianchuan plague focus. The total flea prevalence was 27.60%, the flea prevalence and flea index were highest in winter (299, 45.14%, and 1.01 respectively) and lowest in autumn (105, 14.13%, and 0.24, respectively). The difference in total flea prevalence among small mammals in the two plague foci were not significant (Chi-squared test, \( P=0.159 \)). The numbers of seasonal composition on small mammals and parasitic fleas in the two plague foci were significantly different, respectively (small mammals, Chi-squared test, \( P<0.01 \), parasitic fleas, Chi-squared test, \( P<0.05 \)).
Table 1: Small mammals and parasitic fleas captured in the Yulong and Jianchuan plague focus in the Yunnan province.

| Plague foci | Season  | Number of traps placed | Number of traps collected | Capture efficiency rate (%) | Number of small mammals captured | Small mammal density (%) | Number of small mammals with fleas | Flea prevalence (%) | Number of fleas collected | Flea index |
|-------------|---------|------------------------|--------------------------|----------------------------|-------------------------------|-------------------------|-----------------------------------|-------------------|--------------------------|------------|
| Yulong      | Spring  | 1346                   | 1330                     | 98.81                      | 188                           | 14.14                   | 54                                | 28.72             | 105                      | 0.56       |

|             | Total   | 5102                   | 5020                     | 98.39                      | 1069                          | 21.29                   | 295                               | 27.60             | 618                      | 0.58       |

Table 2 showed the specific composition and distribution of small mammals in the Yulong and Jianchuan plague foci during four seasons. 18 species of small mammals were captured in the Yulong plague focus, representing 14 genera, 6 families, and 3 orders. *A. chevrieri* (34.95%), *A. draco* (17.99%), *E. miletus* (16.06%), and *A. latronum* (11.76%) were the dominant species. 17 species of small mammals were captured in the Jianchuan plague focus, representing 10 genera, 5 families, and 3 orders. *A. chevrieri* (45.74%), *E. miletus* (33.12%), and *A. draco* (11.60%) were the dominant species. Further, 58 specimens of *E. proditor* were captured in the Yulong plague focus (6.56% of all specimens) but not captured in the Jianchuan focus. During the four seasons, the total numbers of first-three dominant species of small mammals (*A. chevrieri*, *A. draco*, *E. miletus*) in the Yulong and Jianchuan plague focus were significantly different (Chi-squared test, *P*<0.01). In addition, in the Yulong plague focus, the majority of small mammals (309) were captured in autumn (34.95% of all small mammals captured in Yulong focus), but the numbers of small mammals captured during the other three seasons were not much difference. By contrast, the numbers of small animals captured in the Jianchuan plague focus during the four seasons were similar.

Table 2: Seasonal distribution of small mammals in the Yulong and Jianchuan plague focus in the Yunnan province [n (%)].

| Plague foci | Species            | Spring          | Summer          | Autumn          | Winter          | Total          |
|-------------|--------------------|-----------------|-----------------|-----------------|-----------------|----------------|
| Yulong      | *Apodemus chevrieri* | 35 (18.62)      | 98 (50.52)      | 146 (75.25)     | 30 (15.54)      | 309 (34.95)    |
|             | *A. draco*         | 38 (20.21)      | 35 (18.04)      | 18 (9.38)       | 68 (35.23)      | 159 (17.99)    |
|             | *Eothenomys miletus*| 27 (14.36)      | 15 (7.73)       | 47 (23.81)      | 15 (7.77)       | 104 (11.76)    |

|             | *Sciurotamias forresti* | 1 (0.53) | -               | -               | -               | 1 (0.11)       |
|             | Other              | -               | 1 (0.52)        | -               | 4 (2.07)        | 5 (0.57)       |
|             | Total              | 188 (100)       | 194 (100)       | 309 (100)       | 193 (100)       | 884 (100)      |
Table 3 showed the composition and distribution of parasitic fleas in the Yulong and Jianchuan plague foci during four seasons. 9 species of parasitic fleas were collected in the Yulong plague focus, representing 7 genera, 3 families, and 6 subfamilies. *N. specialis specialis* (34.09%), *C. (S.) quadrates* (25.41%), *M. euteles* (14.46%), and *C. (S.) yunnanus* (12.19%) were the dominant parasitic fleas. By contrast, 9 species of parasitic fleas were collected in the Jianchuan plague focus, representing 6 genera, 3 families, and 5 subfamilies. *C. (S.) quadrates* (46.93%), *N. specialis specialis* (28.48%), and *Frontopsylla* (*F.*) *spadix spadix* (10.03%) were the dominant parasitic fleas. *C. (S.) yunnanus* was not collected in Jianchuan focus. The numbers of dominant species of parasitic fleas (*N. specialis specialis*, *C. (S.) quadrates*, *M. euteles*, and *C. (S.) yunnanus*) in the Yulong and Jianchuan plague focus were significantly different in all seasons (Fisher’s exact test, *P* < 0.01). Furthermore, in the Yulong plague focus, the majority of parasitic fleas (198) were collected in winter (40.91% of overall fleas in Yulong focus), and the numbers collected during the other three seasons were not much difference. In the Jianchuan plague focus, the majority of parasitic fleas (260) were collected in spring (42.07% of overall fleas in Jianchuan focus), with the second highest collection in winter (28.96% of overall fleas in Jianchuan focus). The numbers collected during the other two seasons were not much difference.

Table 3: Seasonal distribution of parasitic fleas in the Yulong and Jianchuan plague focus in the Yunnan province [n (%)].

| Species                          | Winter | Autumn | Summer | Spring |
|----------------------------------|--------|--------|--------|--------|
| *N. specialis specialis*         | 49 (24.75) | 36 (18.18) | 29 (34.12) | 35 (33.33) |
| *C. (S.) quadrates*              | 70 (14.46) | 59 (12.19) | 36 (18.18) | 48 (45.71) |
| *M. euteles*                     | 54 (27.27) | 59 (12.19) | 36 (18.18) | 4 (3.81) |
| *C. (S.) yunnanus*               | 45 (9.3) | 59 (12.19) | 36 (18.18) | 5 (4.76) |
| *E. spadix spadix*               | 10 (2.07) | 5 (1.03) | 3 (3.13) | - |
| *Stenischia humilis*             | 4 (0.83) | - | 2 (1.01) | 1 (0.95) |
| *Palaepalpsylla remota*          | 3 (0.62) | - | 3 (1.52) | - |
| **Total**                        | 190 (100) | 185 (100) | 96 (100) | 105 (100) |
Table 4 showed the combinations distribution of each small mammal species infected per parasitic flea species in the Yulong and Jianchuan plague foci. 3 species of small mammals had the most parasitic fleas in the Yulong plague focus: *A. chevrieri* (129), *E. miletus* (122), and *E. proditor* (90). Two species of small mammals had the most parasitic fleas in the Jianchuan plague focus: *A. chevrieri* (203) and *E. miletus* (348). The most dominant parasitic fleas were *N. specialis specialis* and *C. (S.) quadratus* in the two plague foci. Simultaneously, *N. specialis specialis* was most frequently found on *A. chevrieri*, and *C. (S.) quadratus* was most frequently found on *E. miletus*. However, in the Yulong plague focus, the most frequent parasitic flea was *N. specialis specialis* (165), followed by *C. (S.) quadratus* (123). The opposite was the case in the Jianchuan plague focus, with 289 specimens of *C. (S.) quadratus* and 174 specimens of *N. specialis specialis*. Of note, 59 specimens of *C. (S.) yunnanus* were collected in the Yulong plague focus but not in the Jianchuan, and 70 specimens of *M. euteles* were collected in the Yulong plague focus but only 6 were collected in the Jianchuan plague focus (Table 5).

Discussion

In this study, we analyzed the composition and distribution of small mammals and parasitic fleas in two plague foci in the Yunnan Province. *A. chevri* was the dominant species of small mammals in the two focal areas, most frequently captured in autumn. *N. specialis specialis* was the dominant parasitic flea in the Yulong plague focus, most collected in summer. *C. (S) quadrus* was the dominant parasitic flea in the Jianchuan plague focus, most collected in spring. It suggests that the two foci have the same dominant host, but the dominant flea species are slightly different. The results are consistent with previous studies, Zhang et al found that *N. specialis specialis* was the dominant parasitic flea in the Yulong plague focus by 2006-2017 surveillance data and Guo et al found *C. (S) quadrus* was the dominant parasitic flea in the Jianchuan plague focus. The main flea difference in the two foci, however, which may be caused by their independent ecological circle [9,25]. This also implied that Yulong focus has a different composition of small mammals and fleas even adjacent to Jianchuan focus, further we need to effort long-term monitoring data to determine whether this composition is accidental or long-term, which to confirm whether impact occurrence of plague.

Furthermore, the flea index in Yulong focus was the most in winter of Yulong focus and in spring of Jianchuan focus had higher average number of parasitic fleas on per small mammal individuals may contribute to higher risk for the occurrence of plague than that in other seasons. *A. chevri* was the dominant species of small mammals in the two foci, most frequently captured in autumn. *A. chevri*, *A. draco*, and *E. miletus* account for most small mammals in the two plague foci. The results are consisted with previously studies, *A. chevri* and *E. miletus* are dominant species of small mammals in the two focal areas [26]. Additionally, it is worth noting that *A. draco* was the dominant species, the captured number was even more than those in *E. miletus* in Yulong focus, previously studies showed that *A. draco* is an invasive species but *E. miletus* is the native species in the middle of the Hengduan Mountains, in order to adapt and survive, *A. draco* needs to constantly adjust its physiological characteristics such as basal metabolic rate [27].

In this study, the mostly increased number of *A. draco* shows maybe its further adapted well to the geographical climate of the Hengduan Mountains, but whether the increase in number will increase the occurrence of animal plague requires long-term monitoring and judgment. Furthermore, *E. proditor* was captured in the Yulong plague focus but not in the Jianchuan plague focus, it might be a secondary host or a popular host, but not be as
the dominant host in the Yulong focus. We also observed some seasonality in species distribution, with the dominant species most abundant in autumn, which may be related to the fall grain harvest. The maturity of food in autumn can provide an ideal habitat and food source for the small mammals, leading to the massive reproduction of small mammals. In general, there were a certain variety similarity between the two plague foci, which A. chevrieri, A. draco, and E. miletus were accounted for most, however, there were obviously differences in the dominant fleas and some small mammals like C. (S.) yunnanus and E. proditor may be associated with geography, local climate, and human interference.

The two main species of parasitic fleas collected in the two plague foci were C. (S.) quadratus and N. specialis specialis. N. specialis specialis was the dominant parasitic flea in the Yulong plague focus but C.(S.) quadratus was the dominant parasitic flea in the Jianchuan plague focus. The results consisted with previously studies [25,28]. Further, while 358 specimens of the top-three species of parasitic fleas (N. specialis specialis, C. (S.) quadratus, and M. euteles) in the Yulong plague focus accounted for 73.96% of all parasitic fleas collected in Yulong focus, they were slightly more prevalent in the Jianchuan plague focus, accounting for 76.38% of all parasitic fleas in Jianchuan focus. In addition, C. (S.) yunnanus species only were collected in the Yulong plague focus, and mostly parasite on E. proditor. Although the dominant parasitic fleas and seasonal distribution of parasitic fleas in the two plague foci were different, in general, the total representation species were similar. That may be because the two foci formed a small independent environment, respectively.

We observed seasonality of parasitic flea abundance, with the dominant flea species in the Yulong plague focus reaching a peak in winter, and the dominant flea species in the Jianchuan plague focus reaching a peak in spring. The parasitic fleas in the Yulong and Jianchuan plague focus showed different seasonality, indicating that a seasonal variation in vectors may be closely related to the local climate, which is in line with the seasonal distribution of plague in the Yunnan province. In addition to acceleration of other anthropogenic changes, acceleration of the climate change is an important factor in the current rise in the spread of infectious diseases and the risk of global outbreaks [29-31]. Simultaneously, while Y. pestis is essential for plague occurrence, the bacterium only establishes itself in areas with a suitable landscaping and climatic conditions, with sufficient small mammals and parasitic fleas to allow epizootic transmission [32]. Recent studies have identified the different vegetation, climate variables and landscape of the plague focus, and to define regions that the risk will increase when human exposure to plague bacteria in the plague focus [33-40].

The main predictors of plague outbreaks in Uganda and Tanzania are elevation and vegetation, as revealed by local spatial-scale studies [41]. The growth of vegetation, precipitation and climatic variables are varying with the season changing, this could indicate that the seasonal variation of host animals and vectors may be closely related to the local climate and precipitation, and these factors are closely linked to the local geographical environment in the Yulong and Jianchuan plague foci. The two plague foci are located close to one another. However, while similar geographical environment may result in a similar small mammal composition, the difference in climate may lead to differences in small mammal density. Further, the vegetation in the Yulong plague focus is mainly alpine pine forest or mixed forest. Because of the complex environment in the area, it has its own special climate, and the temperature and humidity changes are little, protecting small mammals from the cold. The vegetation is denser providing abundant food for small mammals. Additionally, the average altitude in Yulong focus is higher than Jianchuan focus, human interference in high-altitude areas with rich vegetation, and high diversity and evenness indices is relatively low, with obvious boundary effects and community stability [21].

Hence, the Yulong plague focus hosted more small mammal species than the Jianchuan plague focus. Further, high altitude and low population density may have created a suitable environment for small mammals to live and reproduction. The difference of altitude and the low-lying valley in the center of the two focal areas may have been led to the formation of unique environment in the two plague foci, with differences in precipitation. Precipitation is used to affects the growth of primary vegetation, thus influencing the potential food source of small mammals and habitat environment [42,43]. With an increasing or decreasing number of small mammals, flea infection rates rise or fall, accordingly. In addition, an increasing in soil moisture may increase the daily survival rate of fleas, increasing the likelihood of infectious fleas and the contact rate among susceptible hosts, thereby increasing the likelihood of the occurrence of plague [44,45]. The evidence of a link between meteorological variables, small mammal density, and risk of infection outbreaks is compelling [46].

Consequently, because of the difference in seasonal precipitation brought about by the respective unique environments, the parasitic fleas in the Yulong and Jianchuan plague focus were different. The observation that C. (S.) yunnanus (mainly on E. proditor) specimens were collected in the Yulong plague focus (mainly in winter) and not in the Jianchuan plague focus, indicated that this species may be the dominant species of E. proditor, but this notion requires further research. In the two plague foci, more specimens of M. euteles were collected in the Yulong plague focus than that collected in the Jianchuan plague focus. That could be because, first, M. euteles mainly parasitized Dremomys pernyi, predominantly captured in the Yulong plague focus, and, second, M. euteles might be better adapted to survival in the geographical landscape in the
Yulong plague focus than that in the other focus. However, this also requires further research. Small mammals and parasitic fleas are the inevitable factors maintain Y.pestis in a plague focus, while the habitat/landscape, climate variables and pathogenic characteristics determine the properties and structures of the plague focus [47].

Guo, Song, Dong, et al reported that the Yulong plague focus is adjacent to the Jianchuan plague focus, almost forming a single focus. However, a Y. pestis strain isolated in the Yulong plague focus can utilize glycogen and maltose via glycolysis, which is quite different from that of the wild-type Y. pestis strain in the Yunnan province [10,48,49]. Further, Y. pestis strain which isolated from the Yulong is similar to that found on Marmota (Ma.) himalayana in Tibet, and the plague focus of Ma. himalayana and the Yulong plague focus are both located in mountainous regions [48]. Previously, we demonstrated that the Y. pestis strains in the Yulong plague focus are different from the Jianchuan plague focus strains, with a similar geographical landscape, and that the Yulong strains are highly similar to those in the Qinghai Tibetan Plateau plague focus [10,13,50-52]. Therefore, Y. pestis from the Yulong plague focus may have migrated from Ma. himalayana in Tibet via small mammals, and the difference in Y. pestis strains may have led to subtle differences in the properties and structures of the Yulong and Jianchuan plague focus.

This present study has certain strength. First of all, we compared the composition and seasonal distribution of small mammals and parasitic fleas in two similar and adjacent wild rodent foci, but found that although the two places are similar, the existence of species in each season is obviously different. This may be due to the two place is separated by a canyon geographically, which has led to climate change, but further research is still needed. Secondly, our research is different from previous studies on plague foci. We focus more on observing the population of small mammals and fleas in the four seasons, and we can find the number and changes of small mammals and fleas in different seasons. This also provides a scientific basis for local government to effectively implement small mammals and flea control. We also have certain limitations, however, because we are a cross-sectional study, we cannot prove the causality. Secondly, we have only investigated for a year, and the conclusions we got need more time to monitor to be corroborated. This time we only roughly divided into four seasons to collect small mammals and parasitic fleas, but did not carefully analyze the differences in temperature, humidity, and food in each season. These may affect the composition of small mammals and fleas. Our team next step will consider take these factors into further analysis.

Conclusion

The dominant species of small mammals in the two plague foci were identical, with a similar variety of species, suggesting similar small mammal composition in the two foci. A. chevrieri, A. draco, and E. miletus were the dominant small mammals in the two plague foci. In Yulong focus, A. draco thrives better and E. proditor was only a secondary host or popular host. The dominant species of parasitic fleas were different in the two plague foci, but the total variety of species was similar; N. specialis specialis and C. (S.) quadratus were the common dominant vectors. From epidemiological perspective, Yulong focus is adjacent to Jianchuan focus, but there are differences of composition and distribution on small mammals and parasite fleas, these indicating that complicated and uncertainty on wild rodents plague focus, We need to fully understand the proportions and structure of the Yulong focus, especially the distribution of small mammals and parasite fleas may contribute to prevent and control the spread from animal plague to humans.

Ethics Statement

The study has been approved the Medical Ethics Committee of Dali University and performed in accordance with the Rules for Implementation of Laboratory Animal Medicine (1998) from the Ministry of Health, China. The captured of small mammals and parasitic fleas were allowed and no painful.

Consent for publication

Not available.

Availability of Data and Materials

The datasets used and analyzed during the current study are available from the corresponding author on reasonable request.

Competing Interests

The authors declare that they have no competing interests.

Funding

The study was supported by the National Natural Science Foundation of China (No. 81860565; No. 81460485), The Scientific and Technological Innovation team of Natural Focal Diseases Epidemiology in Universities of Yunnan province, The Innovation Team of Natural Focal Diseases Epidemiology in Dali University (No. ZKPY2019201). The funders had no role in the study design, data collection and analysis, decision to publish or preparation of the manuscript.

Acknowledgement

The author would like to express thankfulness to Jianchuan Station for Endemic Disease Control and Prevention and Yulong Center for Disease Control and Prevention.

Author’s Contribution

JXY conceived the project and obtained the funding, QFZ, ZFW, DDX, MDW, YZ ZXL, MH and RDH collected the data, YYL, QFZ,
STL and QNH analyzed the data, YYL and QFZ wrote the paper, JXY revised the paper. All authors read and approved the final manuscript.
