Why is non-Gaussianity interesting? One of generic predictions from inflationary scenarios is that primordial fluctuations are exactly Gaussian in linear order; however, the non-linearity in the inflation will produce weak non-Gaussianity. Thus, measuring the non-Gaussianity in the cosmic microwave background radiation anisotropy is a probe of the non-linear physics in the very early universe. Since the angular three point function is zero for the Gaussian field, it is sensitive to the non-Gaussianity. We predict its harmonic transform counterpart, the angular Bispectrum, down to arcminutes angular scales, including the full effect of the radiation transfer function. We find that even the Planck experiment cannot detect the primary bispectrum from the inflation, as long as the single field slow-roll inflation is right. Non-linearities in the low redshift universe also produce the non-Gaussianity. We find that secondary bispectra are detectable by both MAP and Planck experiments. The secondary bispectra probe the non-linear physics of the low-redshift universe. Although this could be a contaminant to the primary signal, MAP and Planck experiments are found to be able to separate the primary from secondary effects well. We present a tentative comparison of the primary bispectrum to the published COBE 4 year bispectrum. The data put a weak constraint on the parameter, and the constraint would become much tighter when we use all modes available in the COBE data, and certainly forthcoming satellite experiments. As a conclusion, the bispectrum is a key measure to confirm or destroy the simple inflationary scenario in non-linear order that seems quite successful in linear order.

1 The CMB non-Gaussianity from inflation

1.1 Order-of-magnitude estimation of the non-linear coupling parameter $f_{NL}$

We briefly consider the mechanism producing the primary CMB non-Gaussianity from the inflation. Since the observed CMB anisotropy $\Delta T/T$ is thought to be generated by curvature perturbations $\Phi$, the primary non-Gaussianity should be encapsulated in $\Phi$. The inflation makes $\Phi$ weakly non-Gaussian. However, even if $\Phi$ is Gaussian, $\Delta T/T$ can be non-Gaussian.

$\Delta T/T$ is related to $\Phi$ through the non-linear relation:

$$\frac{\Delta T}{T} \sim g_T \left( \Phi + f_\Phi \Phi^2 \right),$$

where $g_T$ is the radiation transfer function converting $\Phi$ to $\Delta T/T$. $g_T = -1/3$ for the Sachs-Wolfe effect. The second term with $f_\Phi \sim O(1)$ is the higher order correction that arises from the second order gravitational perturbation theory. Thus,
it makes $\Delta T$ weakly non-Gaussian, even when $\Phi$ is Gaussian. $\Phi$ is actually a weakly non-Gaussian field, and thought to be produced from the inflaton fluctuations $\delta \phi$ through the relation

$$\Phi \sim m_{pl}^{-1} g_{\Phi} \left( \delta \phi + m_{pl}^{-1} f_{\delta \phi} \delta \phi^2 \right).$$

(2)

g_{\Phi} \sim \mathcal{O}(10)$, and $f_{\delta \phi} \sim \mathcal{O}(10^{-1})$ for a class of slow-roll inflationary scenarios with the single inflaton field. If the dynamics of $\delta \phi$ field is simple enough to keep itself Gaussian throughout the evolution, then we can stop our consideration here. However, in generic, the non-trivial form of the interaction term in the equation of motion, or the non-linear coupling between the coarse-grained classical fluctuations and the fine scale quantum fluctuations, make $\delta \phi$ weakly non-Gaussian, even if it is originally Gaussian field. The result is simply written as

$$\delta \phi \sim g_{\delta \phi} \left( \eta + m_{pl}^{-1} f_{\eta} \eta^2 \right),$$

(3)

where $\eta$ is Gaussian, $g_{\delta \phi} \sim 1$, and $f_{\eta} \sim \mathcal{O}(10^{-1})$.

It is then useful to rewritten equations (1)–(3) as

$$\Delta T \sim g_T \left[ \Phi_L + \left( f_{\Phi} + g_{\Phi}^{-1} f_{\delta \phi} + g_{\Phi}^{-1} g_{\delta \phi}^{-1} f_{\eta} \right) \Phi_L^2 \right],$$

(4)

where $\Phi_L \equiv g_{\Phi} g_{\delta \phi} \eta \sim 10 \eta$ is the Gaussian part of curvature perturbations. More specifically, we define the non-linear coupling parameter, $f_{NL}$, as

$$\Phi(x) = \Phi_L(x) + f_{NL} \left( \Phi_L^2(x) - \langle \Phi_L^2(x) \rangle \right),$$

(5)

where the angular bracket denotes the statistical ensemble average. Note that $f_{NL} \sim f_{\Phi} + g_{\Phi}^{-1} f_{\delta \phi} + g_{\Phi}^{-1} g_{\delta \phi}^{-1} f_{\eta}$, and the first term $\sim \mathcal{O}(1)$ from the second order gravity effect is dominant compared to other two terms from slow-roll inflation $\sim \mathcal{O}(10^{-2})$. $f_{NL}$ corresponds to $\alpha_{\Phi}$ in Verde et al. [4].

1.2 The reduced angular bispectrum

We use the angular bispectrum, harmonic transform of the angular three point function, as a measure of the CMB non-Gaussianity.

$\Delta T(\hat{n})/T$ in the sky is expanded into the spherical harmonics: $\Delta T(\hat{n})/T = \sum_l a_l Y_l(\hat{n})$. $a_l$ is then written in terms of $\Phi$-field,

$$a_l = 4\pi (-i)^l \int \frac{d^3k}{(2\pi)^3} \Phi(k) g_{TT}(k) Y_l^*(\hat{k}).$$

(6)

$\Phi(k)$ is weakly non-Gaussian field given by the Fourier transform of equation (5). Instead of assuming the Sachs-Wolfe’s $-1/3$ law for $g_{TT}(k)$, we use the full $g_{TT}(k)$ down to small scales by solving the Boltzmann transport equation with the CMB-FAST code. We then define the reduced angular bispectrum $b_{l_1 l_2 l_3}$ as

$$b_{l_1 l_2 l_3} \equiv \frac{4\pi}{(2l_1 + 1)(2l_2 + 1)(2l_3 + 1)} \left( \begin{array}{ccc} l_1 & l_2 & l_3 \\ 0 & 0 & 0 \end{array} \right)^{-1} \sum_{m_1 m_2 m_3} \left( \begin{array}{ccc} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{array} \right) (a_{l_1 m_1} a_{l_2 m_2} a_{l_3 m_3}),$$

(7)
Figure 1 plots the equilateral case ($l_1 = l_2 = l_3 \equiv l$) reduced bispectrum. The acoustic oscillation in $g_T(k)$ appears in $b_{lil}$. For the scale invariant $\Phi_L$-field power spectrum,

$$b_{lil}^{primary} \sim 10^{-17} f_{NL} \times l^{-4}, \quad (8)$$

apart from the oscillation and the Silk damping.
2 The CMB non-Gaussianity from low-redshift universe

Secondary bispectra from the coupling between the Sunyaev-Zel’dovich (SZ) effect and the weak lensing effect are found to be marginally detectable by MAP, while Planck will detect them significantly. We give the explicit form of the SZ–lensing coupling bispectrum in the reference. It is roughly

\[ b_{\text{sz-lens}} \sim 10^{-19} j_\nu T_{\rho 0} b_{\text{gas}} \times l^{-3}, \] (9)

up to \( l \sim 1000. \) \( T_{\rho 0} \sim 0.3 \) is the present day density weighted mean temperature in units of 1 keV, while \( b_{\text{gas}} \sim 6 \) is the linear gas pressure bias. \( j_\nu \) is the spectral function of the SZ effect, and equals \(-2\) in the Rayleigh–Jeans regime.

The CMB bispectrum from extragalactic point sources is easy to estimate, as long as they are assumed to be Poisson distributed. The reduced bispectrum is just constant in that case, i.e., \( b_{\text{ps}}^{l_1 l_2 l_3} = b_{\text{ps}} = \text{constant}. \) Detailed arguments are summarized in the reference. The results are

\[ b_{\text{ps}}(90 \text{ GHz}, < 2 \text{ Jy}) \sim 2 \times 10^{-25}, \] (10)

\[ b_{\text{ps}}(217 \text{ GHz}, < 0.2 \text{ Jy}) \sim 5 \times 10^{-28}. \] (11)

Equations (10) and (11) correspond to MAP and Planck experiments, respectively, after subtracting > 5\( \sigma \) sources from the map.

Figure 1 plots \( b_{\text{sz-lens}}^{l_1 l_2 l_3} \) in the Rayleigh–Jeans limit and \( b_{\text{ps}}. \) Clearly, secondary sources dominate the primary signal as going to smaller angular scales, even if \( f_{\text{NL}} = 100 \) is taken. This is opposite to the CMB power spectrum that is dominated by either the primary CMB or the instrumental noise at all \( l \) in the COBE, MAP, and Planck experiments. Thus, we need to separate the primary bispectrum from secondary bispectra. Fortunately, the shapes of bispectra are fairly different, so that we can discriminate among them based on shapes.

3 Can we detect/separate the CMB bispectra?

Since the CMB bispectrum is very weak compared to the Gaussian noise from CMB itself, it is totally hopeless to measure \( b_{l_1 l_2 l_3} \) per mode. Instead, we fit the observed data by theoretical bispectra, and then constrain parameters. For this purpose, we minimize \( \chi^2 \) given by

\[ \chi^2(A_i) \equiv \sum_{2 \leq l_1 \leq l_2 \leq l_3} \frac{\left( B_{l_1 l_2 l_3}^{\text{obs}} - \sum_i A_i B_{l_1 l_2 l_3}^{(i)} \right)^2}{\sigma_{l_1 l_2 l_3}^2}, \] (12)

where \( i \) denotes a component such as the primary, the SZ and lensing effects, extragalactic sources, and so on. In case that the non-Gaussianity is small, the cosmological variance of the bispectrum \( \sigma_{l_1 l_2 l_3}^2 \) is given by the six-point function of \( a_{lm} \). \( \sigma_{l_1 l_2 l_3}^2 \) is dominated by either the primary CMB or the instrumental noise, while
Table 1. The signal-to-noise ratio for the detection of bispectra. \( f_{NL} \) is the non-linear coupling parameter (Eq. (5)). \( T_{\rho_0} \sim 0.3 \) is the present day density weighted mean temperature in units of 1 keV, while \( b_{gas} \sim 6 \) is the linear gas pressure bias. \( j_\nu \) is the spectral function of the Sunyaev-Zel'dovich effect that has \(-2\) in the Rayleigh–Jeans regime. \( b_{ps}^{25} \equiv b_{ps}/10^{-25} \), and \( b_{ps}^{27} \equiv b_{ps}/10^{-27} \), where \( b_{ps} \) is the reduced Poisson bispectrum.

| primary | SZ-lensing | point sources |
|---------|------------|---------------|
| COBE    | 1.7 \times 10^{-3} f_{NL} | 1.8 \times 10^{-4} | 1.7 \times 10^{-7} b_{ps}^{25} |
| MAP     | 5.8 \times 10^{-2} f_{NL} | 0.34 | 2.2 b_{ps}^{25} |
| Planck  | 0.19 f_{NL} | 6.2 | 52 b_{ps}^{27} |

Table 2. The signal degradation parameters. \( d_i \) is defined so as \( d_i = 1 \) for perfectly separated component, while \( d_i > 1 \) for poorly separated one.

| primary | SZ-lensing | point sources |
|---------|------------|---------------|
| COBE    | 1.36 | 3.89 | 3.45 |
| MAP     | 1.01 | 1.16 | 1.14 |
| Planck  | 1.00 | 1.00 | 1.00 |

the secondary sources are subdominant as long as COBE, MAP, and Planck experiments are considered. Taking \( \partial \chi^2/\partial A_i = 0 \), we obtain the Fisher matrix,

\[
F_{ij} \equiv \sum_{2 \leq l_1 \leq l_2 \leq l_3} \frac{B_{i1}^{(i)} B_{j1}^{(j)}}{\sigma_{i1}^2}. \tag{13}
\]

Since the covariance matrix of \( A_i \) is \( F_{ij}^{-1} \), we define the signal-to-noise ratio \( (S/N)_i \equiv 1/\sqrt{F_{ii}^{-1}} \) for a component \( i \), and the signal degradation parameter \( d_i \equiv F_{ii} F_{ii}^{-1} \) due to a contamination from correlated components. \( d_i \) is defined so as \( d_i = 1 \) for perfectly separated component, while \( d_i > 1 \) for poorly separated one. Table 1 and 2 summarize \( (S/N)_i \) and \( d_i \), respectively, for COBE, MAP, and Planck experiments. In order to obtain \( (S/N)_{primary} > 1 \), \( f_{NL} > 600, 20, \) and \( 5 \) are needed for COBE, MAP, and Planck experiments. As derived in section 1.1, the single field slow-roll inflation generally predicts \( f_{NL} \sim O(10^{-2}) \), while the second order gravity yields \( f_{NL} \sim O(1) \). Therefore, either way, the detection is not expected for those experiments.

\( (S/N)_{SZ-lens} \sim 1 \) and \( (S/N)_{ps} \sim 4 \) are expected for MAP, and \( (S/N)_{SZ-lens} \sim 20 \) and \( (S/N)_{ps} \sim 30 \) for Planck. Thus, the leading contribution to the CMB bispectrum would be from extragalactic point sources. Then, the SZ-lensing contribution would be measured by Planck, yielding a constraint on \( T_{\rho_0} b_{gas} \). This quantity measures the physical state of intergalactic gas pressure that is uncertain at present.

4 Tentative comparison to the COBE 4 year bispectrum

Ferreira, Magueijo, and Górski claimed a significant detection of the equilateral bispectrum at \( l = 16 \) in the publicly available COBE 4 year data. Banday, Zaroubi,
and Górski found that their detection would be ascribed to the systematics associated with the eclipse of COBE satellite. This partly demonstrates that the bispectrum is sensitive to the non-linear effect even including the systematics in data.

Magueijo tabulates a particular configuration of the COBE bispectrum without eclipse data. He tabulates 8 modes of

\[ J_l^3 \equiv \frac{b_{l-1l+1}}{\sqrt{4\pi} C_{l-1} C_l C_{l+1}}. \]  

(14)

for \( l = 4 - 18 \). Figure 2 compares our primary bispectrum to his data. There is no significant detection of \( J_l^3 \) per mode, and then \( f_{NL} \) is constrained as \( f_{NL} < 10^4 \). It should be stressed that only 8 modes were used to constrain \( f_{NL} \) here. Since the total number of modes available in the full COBE bispectrum is 466 up to \( l = 20 \), the constraint on \( f_{NL} \) becomes much tighter than \( < 10^4 \), say, \( 1 \sigma \sim 600 \) as suggested by our estimation (table 1). MAP and Planck will certainly put a very stringent constraint on \( f_{NL} \), and thus test the inflationary scenario in non-linear order.

5 Discussion

What if the primary bispectrum is detected? In other words, what if \( f_{NL} \gg 1 \) is measured? One might suspect the systematics, as already demonstrated in the COBE data, or foreground secondary sources. Since we fit the theory to the data, the goodness-of-fit value of \( \chi^2 \) at the best-fit \( f_{NL} \) would tell us whether detected signal is really primary or not. If it passes the \( \chi^2 \) test, then the most straightforward consequence is that — the single field slow-roll inflation is not right.
