ABSTRACT

The nature of various plausible causal links between sympathetic events is still a controversial issue. In this work, we present multiwavelength observations of sympathetic eruptions, associated flares, and coronal mass ejections (CMEs) occurring on 2013 November 17 in two close active regions. Two filaments, i.e., F1 and F2, are observed in between the active regions. Successful magnetic reconnections, caused for different reasons (flux cancellation, shear, and expansion) have been identified during the whole event. The first reconnection occurred during the first eruption via flux cancellation between the sheared arcades overlying filament F2, creating a flux rope and leading to the first double-ribbon solar flare. During this phase, we observed the eruption of overlying arcades and coronal loops, which leads to the first CME. The second reconnection is believed to occur between the expanding flux rope of F2 and the overlying arcades of filament F1. We suggest that this reconnection destabilized the equilibrium of filament F1, which further facilitated its eruption. The third stage of reconnection occurred in the wake of the erupting filament F1 between the legs of the overlying arcades. This may create a flux rope and the second double-ribbon flare and a second CME. The fourth reconnection was between the expanding arcades of the erupting filament F1 and the nearby ambient field, which produced the bi-directional plasma flows both upward and downward. Observations and a nonlinear force-free field extrapolation confirm the possibility of reconnection and the causal link between the magnetic systems.

Key words: Sun: activity – Sun: filaments, prominences – Sun: magnetic fields

1. INTRODUCTION

Solar filaments or prominences are characterized as cooler, denser plasma structures suspended in the hotter, more-tenuous corona. Filaments and prominences are considered to be the same physical object but observed in the solar disk and off the solar limb, respectively. They always lie above the polarity inversion lines (PILs) at different locations on the Sun, for example, in the active regions, at the boundary of the active regions, or in the quiet regions, which are called, respectively, active region filaments, intermediate filaments, and quiescent filaments (Labrosse et al. 2010; Mackay et al. 2010, and references therein).

Upward magnetic pressure, downward magnetic tension, gravity, and gas pressure gradient forces keep filaments in an equilibrium state in the chromosphere and in the corona (Forbes 2000; Schmieder et al. 2013, and references therein). The filaments could undergo different kinds of eruptions, such as full, partial, failed, or asymmetric eruptions, when the equilibrium breaks (Gilbert et al. 2007; Guo et al. 2010a; Zhang et al. 2015). In a full eruption, the filament material and the associated magnetic field structure escape from the Sun and produce a coronal mass ejection (CME; Gilbert et al. 2000; Schmieder et al. 2015). In a failed eruption, neither the filament material nor the associate magnetic field structure erupts (Török & Kliem 2005; Liu 2008; Liu et al. 2009b; Guo et al. 2010a; Joshi et al. 2013a, 2014a, 2014b; Jiang et al. 2014). Various factors have been identified in failed filament eruptions, such as a slow decrease of the overlying magnetic field (e.g., Török & Kliem 2005), a stronger overlying magnetic field (e.g., Liu 2008), or an asymmetric background magnetic field (e.g., Liu et al. 2009b). More recently, Sun et al. (2015) and Chen et al. (2015) studied several confined flares and eruptions from AR 12192 during 2014 October 18 to 29 and found that the strong confinement of the overlying field may be the cause. In partial eruptions, some parts of the filament magnetic structure erupt while other parts do not erupt, depending on the location of magnetic reconnection over or inside the filament (Gilbert et al. 2000; Gibson & Fan 2006; Tripathi et al. 2009). Asymmetric filament eruptions are eruptions when one leg of the filament erupts while the other one remains anchored on the Sun (Liu et al. 2009c; Joshi et al. 2013a).

Various factors have been observed to be responsible for eruptions, such as filament footpoint rotation (e.g., Török et al. 2013), flux emergence near the filament system (e.g., Chen & Shibata 2000), a large decrease of the photospheric magnetic field strength (e.g., Schmieder et al. 2008), or the transfer of flux from one system to another (e.g., Liu et al. 2012). Based on some observations and simulations, a number of theoretical models have been developed for solar eruptions, such as the tether-cutting (Moore et al. 2001), flux cancellation (van Ballegooijen & Martens 1989; Martens & Zwaan 2001), magnetic breakout (Antiochos et al. 1999), and flux emergence models (Chen & Shibata 2000). Ideal magnetohydrodynamic (MHD) instabilities have also been suggested as the cause for solar eruptions, i.e., kink and torus instabilities (e.g., Török & Kliem 2005; Liu 2008). Successive solar eruptions and flares occurring within a short time with a physical link, either in one complex or in different active regions, are known as “sympathetic events” (Wang et al. 2001, 2007; Moon et al. 2002; Jiang et al. 2011). Sympathetic eruptions have been observed and studied in recent years (Zhukov & Veselovsky 2007; Jiang et al. 2009; Liu et al. 2010).
2009a; Jiang et al. 2011; Schrijver & Title 2011; Shen et al. 2012; Yang et al. 2012). Wang et al. (2001) studied two sympathetic M-class solar flares and associated CMEs that occurred on 2000 February 17 from two different active regions. Liu et al. (2009a) reported successive solar flares and two associated fast CMEs on 2005 September 13 from NOAA AR 10808 and discussed the causal relationship between these eruptions. Schrijver & Title (2011) identified a series of flares and eruptions during 2010 August 1–2 and found that all of these events are connected with a set of separatrices, separators, and quasi-separatrix layers. Jiang et al. (2011) presented observations of three successive filament eruptions from different locations on 2003 November 19 and interpreted these sympathetic eruptions from coronal dimming investigations. Yang et al. (2012) presented detailed observations of two filament eruptions on 2005 August 5 in a bipolar helmet streamer-type configuration and interpreted these eruptions as sympathetic. Shen et al. (2012) reported two sympathetic solar eruptions in a quadrupolar magnetic configuration that occurred on 2011 May 12. In all of these observational studies, some physical links were found between the two sympathetic events. Apart from observational work, there are a few simulations that have been performed to understand sympathetic eruptions more clearly (e.g., Török et al. 2011; Lynch & Edmondson 2013). Török et al. (2011) simulated the sympathetic filament eruptions that occurred on 2010 August 1. Lynch & Edmondson (2013) presented a 2.5D MHD simulation of sympathetic magnetic breakout CMEs in a coronal pseudo-streamer-type magnetic configuration. Among the various proposed interpretations and theories, some involve the removal of high-altitude coronal arches through ideal or resistive processes (Jiang et al. 2009; Schrijver & Title 2011; Török et al. 2011; Shen et al. 2012; Yang et al. 2012), while others involve sequential reconnections between adjacent flux systems (Liu et al. 2009a; Chandra et al. 2011; Liu & Ofman 2014; Dulmasse et al. 2015).

Sympathetic eruptions and flares have been observed but the actual magnetic link and the physical mechanisms of these events are not fully clear. In this work, we present multiwavelength observations and interpretations of two successive eruptions from two different active regions that occurred on 2013 November 17. We discuss the multiple stages of the reconnections that occurred during these eruptions. We focus on the following main questions. (1) What are the reasons behind these sympathetic events? (2) How does the reconnection occur between the arcades and/or the flux rope? (3) What is the role of these interactions/reconnections? We organize our paper as follows. Section 2 deals with the description of the observational data set used in the present paper. The magnetic structure and morphological evolution of the sympathetic eruptions, flares, and associated CMEs are presented in Section 3 with the nonlinear force-free field (NLFFF) extrapolation and the associated results discussed in Section 3.8. The main results and their discussions are presented in Section 4.

2. OBSERVATIONAL DATA SET

We use the Global Oscillation Network Group (GONG) Hα observations for the current study and collect data from the GONG archive (i.e., http://halPHA.nso.edu/archive.html). The archive provides images at 6563 Å wavelength with a spatial resolution of 1′′ and a cadence of around 1 minute (Harvey et al. 2011). The Hα observations are used to study the filament eruption dynamics. For the multiwavelength analysis, we have also used the data observed by the Atmospheric Imaging Assembly (AIA; Lemen et al. 2012), which provides full-disk images in two Ultraviolet (UV), one white-light, and seven Extreme Ultraviolet (EUV) wavelengths. AIA provides EUV images with a minimum cadence of 12 s and a pixel size of 0.6′. Magnetic field data are observed with the Helioseismic and Magnetic Imager (HMI; Schou et al. 2012). HMI images have a spatial resolution of 0.5′ with a minimum cadence of 45 s for the line-of-sight magnetic field and a minimum cadence of 720 s for the vector magnetic field. AIA and HMI are two of the instruments on board the Solar Dynamics Observatory (SDO).

To study the kinematics of the eruptions in the limb view, we use the Sun Earth Connection Coronal and Heliospheric Investigation/Extreme Ultraviolet Imager (SECCHI/EUVI) data. SECCHI/EUVI is an instrument on board the Solar Terrestrial Relations Observatory (STEREO; Wuelser et al. 2004; Howard et al. 2008). It observes the Sun in four wavelengths, i.e., 304, 195, 284, and 171 Å. STEREO-A/EUVI images have a spatial resolution of 1.5′. X-ray data have been taken from the Reuven Ramaty High-Energy Solar Spectroscopic Imager (RHESSI; Lin et al. 2002) and the images have been reconstructed using the clean algorithm with an integration time of around 60 s. To study the CMEs associated with the eruptions, we have used Coronagraph data observed by STEREO-A/COR1 (Howard et al. 2008) and the Large Angle and Spectrometric Coronagraph (LASCO; Brueckner et al. 1995) on board the Solar and Heliospheric Observatory (SOHO).

3. MULTIWAVELENGTH OBSERVATIONS OF THE SYMPATHETIC EVENTS

3.1. Morphology and Magnetic Properties of the Filaments

Two nearby filaments were observed on 2013 November 17 in the southwest part of the Sun (Figure 1). The general structure of the filaments can be seen in Figure 2. This figure displays GONG Hα and SDO/AIA 304 and 171 Å zoomed images of the filaments at ~06:00 UT (Figures 2(a)–(c), respectively). The northward and adjacent southward filaments are represented by “F1” and “F2,” respectively. They are at the border of two different active regions, i.e., NOAA 11893 and 11900, respectively. The GONG Hα image shows the location of the core dark filament material (Figure 2(a)), while the extended filament channels can be seen in SDO/AIA EUV images (Figures 2(b) and (c)). It can be seen that the dark filament material observed in Hα lies in the middle of the extended filament channels. The filament channel could be the projection of the flux rope or cavity, or it could be due to the different behavior of the transition region below the flux rope (Aulanier & Schmieder 2002; Filippov et al. 2015). Different extrapolations of magnetic field lines in the filament environment suggest that the Hα material of filaments is supported in the magnetic dips of a flux rope or sheared magnetic arcade (Aulanier et al. 1998; van Ballegooijen 2004; Guo et al. 2010b). The flux rope is overlaid by arcades in the corona and is anchored in the photosphere by barbs or footpoints created by parasitic polarities close to the PIL. The whole magnetic structure is called a filament system.
The anchoring of the filament footpoints can be identified by comparing the Hα and SDO/AIA EUV observations with an SDO/HMI magnetogram. The approximate locations of the footpoints are pointed out in Figure 2(b) where they are clearly visible. We have tracked the contours of the approximate core filament region visible in Hα of both filaments and overplotted in the SDO/HMI magnetogram (Figure 2(d)). The magnetogram represents the line-of-sight component of the Sun’s magnetic field. We have identified the footpoints of the two filaments. It is clear that the northern and southern footpoints of both filaments are anchored in the positive and negative polarity regions in their respective active regions. The northern footpoints of both filaments lie near the centers of the active regions, while the southern footpoints are anchored at the boundaries of the respective active regions. It is also important to note that the filaments are situated along the periphery of the active regions in the disk projection. The magnetic field between the two filaments mostly consists of positive polarity, while the other sides consist mostly of negative polarity.

The two filaments are located in the southern hemisphere, but they have different chirality. Filament F2 is dextral, or, equivalently, the magnetic helicity is negative, for the following reasons. First, the filament forms an inverse J shape as shown in Figure 2. Second, according to the definition in Martin (1998a, 1998b), if one stands at the positive polarity, the axial magnetic field points to the right. Also, the filament barb is right bearing, although it does not have a one to one correlation with the filament chirality (Guo et al. 2010b). On the other hand, filament F1 is sinistral with a similar analysis as for filament F2. Therefore, the chirality of the two filaments is opposite. Also, the chirality of filament F2 is opposite to the dominant helicity sign of active regions in the southern hemisphere, which should be sinistral or positive in the magnetic helicity term (c.f., Martin 1998a, 1998b; Pevtsov et al. 2003; López Ariste et al. 2006).

3.2. Magnetic Field Changes in the Two Active Regions

Figure 3 shows the radial component of the magnetic field at 00:10:11 UT on 2013 November 17. The magnetic field image has been corrected for the 180° ambiguity and the projection effect (Hoeksema et al. 2014). We observe several magnetic field changes in both active regions before the start of the first eruption. All of these changes can be seen very well in the SDO/HMI radial component movie (animation associated with Figure 3). Both active regions show several tiny flux emerging regions. These regions are shown by the northern and southern red ovals. These emerging regions show divergence motions as they expand. In the northern active region, the expansion toward the southwest disturbs the remnant network polarities such as the positive polarity in box 2. We will see the importance of this polarity because magnetic field lines of both filament systems F1 and F2 are anchored in this polarity (see Section 3.8). Moreover, in the northern active region, the following spot is in a decaying phase. It is surrounded by moving magnetic features which form a moat region around it. This moat region is shown by a blue circle in Figure 3. We observed that many small bipoles cancel at the border of the moat region. One of the strong flux cancellation regions is observed in box 1. This cancellation may trigger one reconnection (the third one probably).

3.3. First Eruption and Associated Flare: First Stage Reconnection

The first eruption stage was associated with the activation of filament F2 and the partial eruption of the overlying arcade. Figures 4 and 5 represent the sequence of selected Hα and SDO/AIA 304 Å images showing the overall chromospheric dynamics of the eruptions. Both filaments were located near each other and are represented by the letters “F1” and “F2” (Figures 4(a) and 5(a)). The southward confined motion of the cool plasma of filament F2 started at ~06:45 UT toward its southern footpoint along the filament spine. The heating of the cool plasma (i.e., filament activation) started at ~07:00 UT. The EUV brightness of the filament can be interpreted as the signature of heating (Figures 5(a) and (b)). The confined southward movement of the cool and hot plasma continued until ~07:15 UT (Figures 4(a)–(c), 5(a)–(c)). The partial disappearance of filament F2 during this confined motion has been observed in Hα images (Hα animation and Figure 4(d)). This may also be due to the heating of the cool material of filament F2. The filament activation and heating are believed to be due to reconnection underneath filament F2 between the legs of the overlying sheared arcade.

The reconnection dynamics can be clearly seen in the SDO/AIA 131 Å image sequence (Figures 6(a)–(c)). The SDO/AIA 131 Å channel provides information about the flaring reconnection region in the Sun. The activated filament F2 was visible at ~07:00 UT (Figure 6(a)). The approximate locations where the magnetic reconnection is supposed to occur between the legs of sheared arcades are represented by the white circle and oval in Figures 6(a) and (b), respectively. The reconnection continued and the formation of the flare loops has been observed around ~07:21 UT (Figure 6(c)). These hot flare loops show continuous expansion with the eruption (animation associated with Figure 6). After comparing the cooler and hotter AIA channels, we observed that these flare brightenings and loops only appeared in the hotter AIA channels, i.e., 131 and 94 Å.
The formation of the flare ribbons on both sides of the reconnection region is clearly observed in Hα, SDO/AIA 304 and 1600 Å images (Figures 4(c)–(d), 5(c)–(d), and 6(d), respectively). These ribbons also show apparent separation motion away from each other (see the Hα, SDO/AIA 304 and 1600 Å animations associated with Figures 4–6, respectively). The northern ribbon moves north while the southward ribbon moves southwest. The flare loops connecting the flare ribbons can be observed by comparing SDO/AIA 131 and 1600 Å images (Figures 6(c) and (d), respectively). The extension of the northern and southern ribbons of the first flare have a J shape and can be considered as the hooks of the flux rope containing filament F2. The ribbons shown by the white ovals in Figure 6(d) are the spreading footpoints of the growing flare loops.

In order to understand the temporal evolution of the EUV brightening during the flare events, we estimated the EUV intensity profiles for the flaring region during the period 06:30 UT to 08:30 UT. These temporal profiles of SDO/AIA 304, 131, 171, and 94 Å wavelength channels are presented in Figure 7. For comparison, we overplotted GOES X-ray profiles in 1–8 Å and 0.5–4 Å. Each profile is normalized by different values for better comparison of the flare evolution. The region used for estimating these profiles is shown in Figure 5(e) with a white box. The first flare phase can be considered to last from 07:00 UT to 07:35 UT. A gradual rise started around 07:00 UT in all of the EUV intensity profiles. The SDO/AIA 304 and 171 Å profiles show a continues increase up to around 07:10–07:12 UT. These profiles show a gradual decrease up to 07:35 UT. The SDO/AIA 131 Å profile shows an initial gradual increase up to around 07:10 UT and then remains almost constant up to 07:35 UT. On the other hand, the 94 Å profile shows a consistent gradual increase with a very slow rate up to 07:35 UT. A peak has also been observed in GOES...
profiles, which appear to be consistent with the SDO/AIA 304 and 171 Å profiles. The full-disk observations at the same time reveal that this peak in the GOES X-ray came both from the flare in this study as well as from another flaring activity that occurred in another active region 11897.

We do not see the eruption of the filament material during this phase in SDO/AIA 304 Å and NSO/GONG Hα observations. However, some evidence of the eruption from F2 and coronal loops can be found from SDO/AIA 171 Å and STEREO-A/EUVI 195 Å images (Figures 8 and 9). Figure 8 shows the SDO/AIA 171 Å difference images, showing the eruption of the filament F2 overlying loops between 07:09 UT and 07:15 UT in the disk view (see animation attached with Figure 12). The erupting leading edge of the visible coronal loops is represented by the dashed white curved lines. From the SDO/AIA 171 Å disk observations, we also observe coronal dimming signatures just above filament F2 at 07:11 UT (Figure 8(b)) as well as under the erupting loops at 07:14 UT (Figure 8(c)) and 07:15 UT (Figure 8(d)). The observed coronal dimmings show observational evidence of eruptions from these regions. The locations of flare reconnection are also shown by the red circles in each panels. On the other hand, Figures 9(a)–(e) show the STEREO-A/EUVI 195 Å limb observations of the expansion and eruption of the overlying coronal loops between 07:05:30 UT and 07:45:30 UT. The overlying loops are clearly visible in the limb view at 07:05:30 UT (Figure 9(a)). The expansion and eruption of the filament F2 overlying loops started at ~07:05:30 UT and continued until 07:45:30 UT (animation associated with Figure 9). The approximate leading edge of the erupting overlying loops is shown by the white arrow in each panel. The eruption of the overlying coronal loops is very clear from the STEREO-A/EUVI 195 Å movie. Figure 9(f) shows the height–time profile of the erupting coronal loops using STEREO-A/EUVI 195 Å images. A rough trajectory along which the height–time measurements are performed is shown in Figure 9(d) with the dashed white line. The error bars are the standard deviations estimated using three repeated measurements of the same point. The speed is estimated by the linear fit to these height–time data points. The estimated speed is around 160 km s$^{-1}$. We suggest that after the reconnection between the legs of the sheared arcades, some of the overlying arcades erupted. These arcade eruptions result in the expansion and eruption of the overlying coronal loops.

### 3.4. Interaction between the Magnetic Field of the Two Filaments: Second Stage Reconnection

Simultaneously with the first eruption, the ribbon separation of the first flare continued up to 07:32 UT, as was discussed in detail in Section 3.3. Looking at the 304, 94, and 131 movies, we can see the expansion of the northern ribbon of the first flare, the footprint of the hook of the F2 flux rope end. According to the motion and expansion of the hook of the F2 flux rope, it seems that the first reconnection is continuous even after the first flare, and sucks the field lines between the two flux ropes, forcing some field lines to change connectivity and reconnect far away. During the second stage interaction, we observed several brightenings. At 07:32 UT, we observe the start of a first brightening under filament F1 in the Hα and AIA EUV channels (Figures 4(e), 5(e), 10(a), and (c)). This brightening corresponds to the slight bump in AIA 304, 131, and 171 Å as well as the GOES X-ray profiles during the intermediate time between the two flares (Figure 7). This phase is represented by “IF” in Figure 7. This compact brightening is located at the region where the positive and negative polarities lie near each other (i.e., corresponds to box 1 in Figure 3). It looks like the flux rope containing F1 is heated below and above F1, probably by a second reconnection. At 07:36, we see a second brightening in the south of the first one with a J shape in the 304, 131, and 94 Å channels (Figures 4(e), 5(e), 10(d), and (f)). This could correspond to the flux rope hook of F1 and the elongated brightening could be considered to be heated plasma along the flux rope. Thereafter, the flux rope containing F1 is destabilized and heated.

During the same time, we note a brightening in the box (Figure 10(c)) corresponding to the anchorage of the arcades overlying F1 and F2. The timing of the two brightenings suggests some heating all along the flux rope until its end at the location of the box. We also see some new brightenings above F1 like loops in 131 Å at 07:37 and 07:41 UT (Figures 10(d), (f), (g), and (i)). At the same time, the F1 flux rope (J ribbon) is heated in 304 Å and starts to inflate from 07:41 UT. All of this observational evidence suggests the second reconnection.

### 3.5. Eruption of Filament F1 and the Associated Flare: Third Stage Reconnection

The activation of the northern filament F1 started at around ~07:39 UT, a few minutes after the heating underneath. Thereafter, filament F1 started to rise between 07:42 and 07:43 UT (Figure 11(a)). The eruption of filament F1 was associated with a small C4.9 class solar flare. The low-lying reconnection between the legs of the overlying arcade field lines in the wake of the filament F1 eruption may trigger this flare. This is the third stage of magnetic reconnection. Thereafter, the filament F1 continued to erupt in the same direction as that of the first eruption (Figures 4(f) and (g), 5(f)
and (g), and 11(b)). We find RHESSI X-ray sources of 6–12 (red) and 12–25 (blue) keV over the flare brightening region at around 07:58 UT (Figure 11(c)), which signifies the existence of magnetic reconnection.

A careful inspection of the EUV intensity and GOES X-ray profiles shows that the third stage of enhancement started around 07:43 UT in all of the EUV channels (Figure 7). The GOES X-ray flux enhancement also shows the third stage of enhancement (red curves in Figure 7). SDO/AIA 304 and 171 Å profiles show early peaks around 07:54 UT, while the SDO/AIA 94 and 131 Å and GOES X-ray profiles show the peaks of the flare between 08:00 UT and 08:05 UT. This third

Figure 4. Sequence of selected NSO/GONG Hα images showing the overall evolution of the filaments activities. (An animation of this figure is available.)
enhancement in the EUV profiles is due to the reconnection in the wake of the erupting filament F1 between the surrounding arcades. Moreover, the intensity profiles of the SDO/AIA 94 and 131 Å and GOES X-ray channels also show another enhancement that started around 07:53:11 UT before reaching the peak. This provides evidence for another small

Figure 5. Sequence of selected SDO/AIA 304 Å images showing the overall evolution of the filaments activities. The white box in panel (e) shows the area used for intensity profiles. The newly formed loop system are shown by the black dotted lines in panel (i). The green and blue contours in panel (d) are the SDO/HMI magnetic field contours for positive and negative polarity, respectively. The contour levels are ±50, ±100, ±200, ±300, ±400, and ±500 Gauss. (An animation of this figure is available.)
reconnection stage during its eruption phase. The NOAA record shows that the flare started at \( \sim 07:37 \) UT, peaked at \( \sim 08:01 \) UT, and ended at \( \sim 08:24 \) UT. At about 07:58 UT, we observe that the erupting filament F1 broke into two parts, namely, the lower and upper parts. These upper and lower parts are represented in Figures 4(h), 5(h), and 12(a). Thereafter, we observe the eruption of the upper part only, while the lower part remains stable against eruption (animations associated with Figures 4 and 5). Along with the eruption of the upper part, we observe the simultaneous formation of two ribbons (Figure 11(d)). In the late decay phase at \( \sim 08:30 \) UT, two set of post flare loops have also been observed in the SDO/AIA 171 Å channel (Figure 11(e)). The right set of post flare loops (i.e., loops 1) are associated with the first flare, while the left set of post flare loops (i.e., loops 2) are associated with the second flare. The overall dynamics of both eruptions can be clearly seen in the H\( \alpha \) and SDO/AIA movies (see attached full length movies with Figures 4 and 5).

3.6. Reconnection between the Erupting Filament F1 and the Ambient Field: Fourth Stage Reconnection

The erupting arcades of filament F1 underwent reconnection with the ambient field during \( \sim 07:58 \) UT to \( \sim 08:12 \) UT (Figure 12). This can be interpreted as the fourth stage of magnetic reconnection. Figure 12 represents the SDO/AIA 171 Å running difference images during the period \( \sim 08:01 \) to \( \sim 08:12 \) UT. The eruptive upper and stable lower parts and the surrounding ambient field can be seen at 08:01 UT (Figure 12(a)). The erupting upper part of filament F1 is reconnected with the nearby overlying ambient field lines (Figures 12(b)–(d)). The approximate locations of the reconnection regions are marked by the red circles in each panel. As
a result, the filament plasma appears to show downward and upward flow motions (animations associated with Figure 12). The green arrows in Figures 12(b)–(d) represent the directions of the upward and downward filament plasma motion. We also observe the formation of a new loop system joining the negative footpoint of filament F1 and the nearby positive polarity (Figures 4(i), 5(f), and 12(b)–(d)).

3.7. Kinematics of Filament F1 and Associated CMEs

The left and right panels of Figure 13 show the eruption of filament F1 using on-disk observations by SDO/AIA 304 Å and the limb observations by STEREO-A/EUVI 304 Å, respectively. The arrows in all of the respective panels mark the similar leading edge of the erupting part of filament F1. Both the panels show similar morphological evolution of the filament F1 eruption. Figures 14(a) and (b) show the height–time profiles of the erupting part of filament F1 for on-disk SDO/AIA 304 Å as well as STEREO-A/EUVI 304 Å limb observations during the period 07:30 UT to 08:22 UT. The error bars in these plots are the standard deviations estimated by three repeated measurements of the same point. The rough trajectories along which the height–time measurements have been performed are represented in Figures 13(c) and (f) with dashed white lines. In the height–time profile of SDO/AIA 304 Å, we can identify two stages of the eruption of filament F1, namely, the first slow phase and the second fast phase. It is observed that initially filament F1 erupted with a slow speed during the period 07:41 UT to 08:02 UT (Figures 13(a), (b) and 14(a)). The estimated speed during this phase is around 145 km s\(^{-1}\). It entered the fast eruption phase after 08:02 UT. The estimated higher speed is around 337 km s\(^{-1}\) during 08:02 UT to 08:22 UT (Figure 14(a)). The speed increase is due to the reconnection between the erupting filament F1 with the ambient magnetic field. The reconnection between the erupting filament F1 with the ambient field started around 08:02 UT and continued up to around 08:15 UT, which is consistent with the fast rising phase of filament F1. Figure 14(b) shows the height–time relationship using the STEREO-A/EUVI 304 Å observations during the period 07:48:45 UT to 08:18:45 UT. The estimated speed is \(\sim247\) km s\(^{-1}\). Because of the low cadence, we cannot see the two different phases in this panel. The speeds are calculated using the linear fit to the height–time data points during selected time intervals. The eruption of filament F1 seems to be asymmetric with the fully eruptive northern and anchored southern legs (Figure 13(f)).

Both the first and second eruptions produced CMEs. The first of these eruptions originated from the vicinity of the filament we call F2, and produced the CME that we call CME1. During this first eruption, we observed disruption of filament F2 along with the expulsion of loops above F2, but it is not clear whether F2 itself was ejected or if instead it just faded. Figures 8 and 12 show the erupting loops. The spreading ribbons in Figure 6(d) are the footpoints of the arcade formed as the legs of these erupting loops reconnect, while the loops themselves continue to move outward to form part of CME1. The second eruption started with the eruption of the filament we call F1, and produced the CME we call CME2. In this case, F1 clearly did erupt outward (e.g., Figures 5(f) and (g)). The flare ribbons shown in Figure 11(d) are the footpoints of the arcade formed by this second eruption. Figure 11(e) points out the post flare loops from both the first (post flare loops 1) and the second eruption (post flare loops 2).

Figure 15 represents the sequence of white-light chronograph images of the CMEs. Figures 15(a)–(d) show the STEREO-A/COR1 images from 07:25 UT to 08:25 UT, overplotted with the STEREO-A/EUVI images. Figures 15(e)–(h) represent the SOHO/LASCO C2 and C3 images during the period 08:24 UT to 09:54 UT, overplotted with the SDO/AIA images. All of the panels show the complete sequence of the evolution of the CMEs. At \(\sim07:25\) UT, we observe the dimming and the eruption of the overlying field in the STEREO-A/EUVI image (Figure 15(a)). The eruption was observed in the COR1 field of view at \(\sim07:45\) in the form of CME1 (Figure 15(b)). No core structure was associated with

Figure 7. Intensity profiles of the flaring region in the SDO/AIA 304 (blue), 171 (black), 131 (green), and 94 (orange) Å wavelength channels. The overplotted solid red and dashed red lines represent the GOES 1–8 and 0.5–4 Å profiles for comparison. Different flare phases are also marked. IF represents the intermediate phase between the first and second flares. The vertical dashed lines from left to right correspond to 07:00:11 UT, 07:35:11 UT, 07:43:11 UT, and 07:53:11 UT, respectively.
CME1. The erupting filament F1 was observed at ~08:05 UT in the EUVI field of view while the leading edge of CME1 moved more outward in the COR1 field of view (Figure 15(c)). The erupting filament was seen for the first time in the STEREO-A/EUVI (Figure 15(d)) as well as the LASCO C2 (Figure 15(e)) fields of view around 08:24–08:25 UT. The second CME was associated with a core structure, i.e., the erupting part of filament F1. At ~08:48 UT, we also observe multiple white and dark bands that show the signature of different leading edges and cavities (marked by black arrows in Figure 15(f)). A similar pattern progressed simultaneously (Figures 15(g) and (h)), which suggests that both CMEs produced by different eruptions merged and formed a compound CME structure at the later stages.

3.8. Magnetic Field Modeling

In order to understand the overlying magnetic field configuration, we carried out an NLFFF extrapolation using the optimization method (Wiegelmann 2004; Wiegelmann et al. 2006) over the active regions and present the result in Figure 16. Panels (a) and (b) show the approximate AIA on-disk and STEREO-A/EUVI limb views, respectively, while the bottom panel (c) represents the top view of the active regions with extrapolated field lines. The green and red lines represent the low-lying magnetic field lines over the northern and southern interacting magnetic systems, respectively. The blue lines represent the open field lines and the field lines not concerned with the present events. By comparing Figures 16(c) and 2(d), we note that the magnetic field lines in red are the overlying arcades of filament F2 and the magnetic field lines in green are the overlying arcade field of F1. Some connections between the overlying fields of F1 and F2 have also been observed. The white box shows the region of positive polarity between the active regions. As shown in the top view of the extrapolation result, some magnetic field lines overlying filament F2 extend to the region where some other magnetic
Figure 9. (a)–(e) STEREO-A/EUVI 195 Å running difference images from 07:05:30 UT to 07:45:30 UT showing the eruption of the overlying coronal loops during the first flare. The solid white curved line represents the limb of the Sun. (f) Height–time profile of the erupting loops.

field lines overlying F1 are anchored. This signifies that magnetic interaction can occur between the two filaments. This connection is very important for explaining the second stage of reconnection between the two filament magnetic systems. Second stage reconnection is supposed to occur between the expanding filament system (namely, the magnetic flux rope and the surrounding field lines) of F2 and the overlying magnetic arcades of filament F1.

4. RESULTS AND DISCUSSIONS

The present work deals with the observational analyses and interpretations of sympathetic eruptions, associated flares, and CMEs using multiwavelength data from SDO/AIA, GOES, NSO/GONG, STEREO-A/EUVI, STEREO-A/COR1, RHESSI, and SOHO/LASCO occurring in two active regions on 2013 November 17. We discuss various interactions and
Figure 11. (a)–(c) SDO/AIA 131 Å images showing the evolution of the filament eruption and the triggering of the second flare at 07:42:08 UT, 07:52:56 UT, and 07:58:56 UT, respectively. The green and blue contours in panel (b) are the SDO/HMI magnetic field contours for positive and negative polarity, respectively. (d) SDO/AIA 1600 Å image at 07:58:40 UT showing the flare ribbons of the second flare. The contour levels are ±50, ±100, ±200, ±300, ±400, and ±500 Gauss. The contours in panels (c) and (d) are the RHESSI 6–12 KeV (red) and 12–25 KeV (blue) contours showing the location of the flare. The contour levels are 70%, 80%, and 90% and the integration time is 60 seconds. (e) SDO/AIA 171 Å image at 08:29:59 UT showing the post flare loops associated with the two flares.
reconnections between the filament magnetic field systems and between the filament magnetic field and the surrounding ambient magnetic field during the eruptions. The main results of the study are as follows.

1. Observations clearly show that the two successive eruptions and associated flares can be interpreted as sympathetic events.
2. The magnetic reconnection can be divided into four stages during these sympathetic events. The first stage of reconnection occurred as a flux cancellation between the legs of the sheared arcades of filament F2. This might trigger a two-ribbon solar flare, the eruption of the overlying coronal arcades, and coronal loops.
3. The second stage reconnection could be between the field lines of the expanding flux rope F2 and flux rope F1 as well as with its arcades. It activates F1 with heating signatures all along the flux rope and destabilizes it.
4. The third stage reconnection occurred at the wake of the erupting filament F1 between the legs of overlaying arcades. This may trigger another two ribbon solar flare.
5. The fourth stage of reconnection occurred between the erupting arcades of filament F1 and the nearby

Figure 12. SDO/AIA 171 Å running difference images during the period 08:01:11 UT to 08:12:23 UT showing the eruption of filament F1 and its reconnection with the surrounding ambient medium. The green arrows represent the upward and downward plasma flows from the reconnection region. The reconnection regions are shown by the red circles. The solid white curved line represents the limb of the Sun. The newly formed loop system is represented by the cyan color loops in panels (c) and (d).

(An animation of this figure is available.)
Figure 13. Left panel (a)–(c): SDO/AIA 304 Å running difference images during the period 07:51 UT to 08:18 UT showing the on-disk observations of the filament F1 eruption. Right panel (d)–(f): STEREO-A/EUVI 304 Å images during the period 07:51:15 UT to 08:18:45 UT represent the limb observations of the eruption of filament F1. Arrows mark the leading edge of the erupting part. The dashed lines in panels (c) and (f) show the rough trajectory along which the eruption of filament F1 has been tracked for the height measurement. The solid white curved lines represent the limb of the Sun.
Figure 14. Projected height–time profile of the filament F1 eruption derived by SDO/AIA 304 Å (a) and STEREO-A/EUVI 304 Å (b) images. Red solid and dashed curves in panel (a) show the GOES X-ray profiles in 1–8 and 0.5–4 Å wavelength channels. The first vertical dashed line in panel (a) shows the time of compact brightening under the filament F1 around 07:35 UT. The second vertical dashed line represents the start of filament F1 eruption around 07:43 UT. The third line represents the second stage fast eruption of filament F1 around 08:02 UT. The rough trajectory along which the height measurement is performed is shown in Figures 13(c) and (f) by the dashed white line. The error bars are the standard deviations estimated using three repeated measurements of the same point.

Figure 15. STEREO-A/COR1 ((a)–(d)) and SOHO/LASCO C2 and C3 ((e)–(f)) images showing the sequence of CMEs associated with the first and second eruptions during the period 07:25 UT to 09:54 UT on 2013 November 17. The difference images are collected from the CDAW stereo catalog (http://cdaw.gsfc.nasa.gov/stereo/daily_movies/2013/11/17/index.html) as well as from the SOHO/LASCO catalog (http://cdaw.gsfc.nasa.gov/CME_list/). The black arrows in panel (f) represent the multiple white and black bands, which show the evidence of different parts of the two CMEs.
surrounding ambient field. We believe that the acceleration phase and the asymmetric eruption of filament F1 are consequences of this coronal reconnection.

The present observed eruptions and flares can be interpreted as two consecutive sympathetic eruptions and flares. For sympathetic eruptions, it is required that they should occur in two different active regions and different PILs on the Sun with some physical connections (Jiang et al. 2009, 2011; Liu et al. 2009; Török et al. 2011; Shen et al. 2012; Yang et al. 2012; Lynch & Edmondson 2013). In our case, we observed two eruptions from two different nearby active regions and different PILs (Figure 2). The NLFFF extrapolation shows the presence of overlying field lines of F1 and F2 anchored in the small positive region between them, showing some possible connection between them (see box 2 in Figures 3, 16, and 17). The similar directions of both eruptions within a short time period of ~40 minutes provides additional evidence for sympathetic eruptions. We also observed two flares associated with these sympathetic eruptions, which can also be considered as sympathetic flares. Two different sets of flare loops have been observed close to each other with common anchoring at the central positive polarity region (Figure 11(e)). Hence, the present observations not only show the sympathetic eruptions, but also the sympathetic flares which they produced. Similar types of sympathetic flares associated with two eruptions have also been reported in a few earlier works (e.g., Wang et al. 2001, 2007).

Based on the multiwavelength observations, we identify the four different stages of reconnections during the sympathetic eruptions (see schematic in Figure 17). Figure 17(a) represents the initial magnetic topology of the filaments and the overlying ambient coronal fields. Two nearby filaments (i.e., F1 and F2) exist along with their overlying arcades as well as the surrounding ambient fields (see Figure 2 also). The first flare reconnection seems to be consistent with the low-lying tether-cutting-type reconnection between the sheared arcades leading to the formation of a flux rope (c.f., Moore et al. 2001). The formation of the flare loops and their separation over time can be understood as resulting from reconnection between the legs

Figure 16. NLFFF extrapolation of the two active region photospheric HMI magnetic fields at 07:00:00 UT on 2013 November 17 viewed from three different angles, i.e., (a) the AIA view, (b) the approximate STEREO view, and (c) the top view. The white box is the approximate box 2 in Figure 3. It shows the positive polarities where the overlying arcades of F1 (green lines) and those of F2 (red lines) are anchored.
Figure 17. Schematic representation of the sympathetic eruptions and associated flares. Blue and pink lines represent the nearby ambient magnetic field lines. Green and red lines show the overlying arcades of filaments F1 and F2, respectively. Black lines represent the reconnected field lines. Brown lines show the flare ribbons. The approximate times corresponding to the real observations are mentioned in each panel.
of the surrounding field as the flux rope of that first eruption moves outward to form CME1. The growing flare loops and the spreading flare ribbons are observational signatures of this first reconnection (see animations accompanying Figure 6). Our observations show that the first eruption, which led to this first reconnection, began near filament F2 but there is no clear ejection of F2. Apparently, F2 was located below the field that erupted in that first eruption. Similar kinds of eruptions have been discussed in observational studies (e.g., Pevtsov 2002; Tripathi et al. 2009; Schmieder et al. 2015). Some of them have been interpreted with the partial eruption model of flux ropes (Gibson & Fan 2006; Tripathi et al. 2009).

The second stage of reconnection is the most difficult to explain and it is not obvious where it happened. What we are sure of is that there is an interaction between both systems (Figure 17(d)) and the flux rope of F2 destabilizes the F1 system. Various observational signatures of the second interaction and reconnection were discussed in Section 3.4. It has been observed that the removal of overlying field lines during the first eruption plays a crucial role in triggering a nearby eruption (e.g., Jiang et al. 2009, 2011; Yang et al. 2012). Some studies proposed that the external breakout-type magnetic reconnection during the first eruption, either in quadrupolar magnetic configuration (Shen et al. 2012) or in unpolar helmet streamer (Török et al. 2011; Yang et al. 2012; Lynch & Edmondson 2013) magnetic configuration, may be responsible for the other nearby successive eruption by removing the overlying flux. On the other hand, the sucking of the field lines over F1 by the first reconnection is also a factor diminishing the tension (green field lines over F2 in Figure 17(c)). There was probably a driving reconnection pushing the two systems together. This kind of reconnection is only possible in three dimensions, as shown in MHD simulations for other event sequences (Török et al. 2011).

The third stage of reconnection is believed to occur during the eruption of filament F1 and has some similarity to the first stage of reconnection occurring in the F2 system (Figures 11(b)–(d) and 17(e) and Section 3.5). This reconnection may be consistent with the standard CSHKP flare model by filament or flux rope eruption (c.f., Carmichael 1964; Sturrock 1966; Hirayama 1974; Kopp & Pneuman 1976). According to this, during the eruption of filament or flux rope, the reconnection between the legs of the surrounding arcades in the wake may trigger a solar flare.

The erupting arcades of filament F1 also reconnected with the nearby ambient magnetic flux (Figure 17(f)) and formed another new loop system (Figure 17(f)). We interpret this reconnection as the fourth stage of reconnection (refer to Section 3.6 for detail). This reconnection can be interpreted between the ambient open field lines with the filament F1 growing arcades in the corona. A similar kind of coronal reconnection scenario has been discussed by Vrsnak et al. (2003) in interpreting the filament eruption of 2000 September 12. Recently, for the first time, van Driel-Gesztelyi et al. (2014) found evidence of reconnection in the corona between the field lines of two different active regions during CMEs. They also identified the bright coronal region of reconnection as well as the cool down flowing plasma. In our case, we also find the observational signature of coronal reconnection via the bi-directional flow of filament F1 plasma after the arcade reconnection with the ambient magnetic field (Figure 12 and associated animations). We also believe that this reconnection was responsible for the acceleration phase of the eruptive part of filament F1 (Section 3.7 and Figure 14(a)). This result suggests that this kind of coronal magnetic field reconnection may play an important role in accelerating the filament speed during its eruption. This reconnection is also believed to occur for the asymmetric eruption of filament F1. We observed that the northern leg of filament F1 erupted fully, while the southern leg remained anchored on the Sun (Figure 13). We believe that the interaction and reconnection of the erupting southern part of filament F1 with the ambient magnetic field caused the eruption asymmetry. This is a different mechanism compared to the whipping-and-zipping-type model of asymmetric filament eruption given by Liu et al. (2009c). In the end, three different types of loop systems are formed, i.e., two post flare loops and one newly formed loop system (Figures 11(e), 12(c), and 17(g)).

Another interesting result is that filament F1 broke into two different parts, i.e., the erupting upper and stable lower parts (Figures 4(h), 5(h), and 12(a)). We suggest that the reconnection of the erupting filament F1 with the surviving field of F2 may break F1 into two parts. Also, the observed enhancement in the brightness of the southern ribbon of the first flare during the eruption of filament F1 also provides some hint for this type of interaction (Figure 11(d)).

We also observe that the second fast eruption (speed ~377 km s\(^{-1}\)) overtook the first slow eruption (160 km s\(^{-1}\)) and the associated CMEs merged and formed a compound CME (see Section 3.7 and Figure 15). The compound CME structure can be seen at 08:48 UT and onward with multiple leading edges and cavities (Figures 15(f)–(h)). These observations suggest that the sympathetic nearby eruptions and associated CMEs in the same directions can also lead to interesting CME–CME interaction events in the corona near the Sun. These interactions have great importance for the production of solar energetic particle events (e.g., Gopalswamy et al. 2001; Joshi et al. 2013b; Masson et al. 2013).

The study of nearby eruptions, flares, and CMEs provides us with important information about magnetic interactions and the reconnections between them. We have identified several physical mechanisms for producing this sequence of sympathetic events in two different active regions: canceling flux, shear arcades, and inflation or expansion of magnetic field systems. In this study, all of these mechanisms work together or successively between the different magnetic systems. It provides a good example of sympathetic events. These kinds of observational studies also provide important input for MHD modeling of sympathetic eruptions and the associated flares. High-resolution observations and more numerical simulation studies are needed to understand the sympathetic events more clearly.

The authors thank the referee for providing valuable comments and suggestions. We thank the SDO/AIA, SDO/ HMI, STEREO/SECCHI, NSO/GONG, SOHO/LASCO, GOES, and RHESSI teams for providing their data for the present study. This work is supported by the BK21 plus program through the National Research Foundation (NRF) funded by the Ministry of Education of Korea. N.C.J. thanks the School of Space Research, Kyung Hee University for providing the postdoctoral grant. Y.G. is supported by NSFC 11203014 and 11533005 and BELSPO postdoctoral grant. Y.G. thanks the Observatoire de Paris. We are thankful to
Dr. Tibor Török for valuable suggestions and comments on the present work.
