Abstract

The genetic basis of sex-specific differences in wing size between two closely related species of *Nasonia* by positional cloning a major male-specific locus, wing-size1 (wsl). Male wing size increases by 45% through cell size and cell number changes when the *wsl* allele from *N. giraulti* is backcrossed into a *N. vitripennis* genetic background. A positional cloning approach was used to fine-map the *wsl* locus to a 13.5 kilobase region. This region falls between *prospero* (a transcription factor involved in neurogenesis) and the master sex-determining gene *doublesex*. It contains the 5' UTR and cis-regulatory domain of *doublesex*, and no coding sequence. Wing size reduction correlates with an increase in *doublesex* expression level that is specific to developing male wings. Our results indicate that non-coding changes are responsible for recent divergence in sex-specific morphology between two closely related species. We have not yet resolved whether wing size evolution at the *wsl* locus is caused by regulatory alterations of *dsx* or *prospero*, or by another mechanism. This study demonstrates the feasibility of efficient positional cloning of quantitative trait loci (QTL) involved in a broad array of phenotypic differences among *Nasonia* species.

Introduction

Somatic sexual differentiation is an ancient feature of animals, yet sex differences in morphological traits can evolve rapidly. Because of this, between-species genetic analysis of recently evolved sexual differences has been proposed as a way of identifying the genes and genetic changes that underlie morphological diversification [1]. For example, Kopp et al. [2] have found that a sex-specific abdominal pigmentation difference that recently evolved between *Drosophila* species is caused by non-coding cis-regulatory changes in the *bric-a-brac* gene, changes which involve binding sites for conserved transcription factors *doublesex* and *ABD-B* [3]. The study of recently evolved sex differences can therefore reveal changes in tissue- and sex-specific gene regulatory networks. Nevertheless, there have been few studies investigating the genetic and molecular basis of the recent evolution of morphological differences between species, due in part to the difficulty of conducting genetic analyses in diverged species that are often reproductively incompatible.

An active debate concerns whether the evolution of differences between species are due primarily to cis-regulatory or protein-coding changes (e.g., [4–8]). While protein-coding changes have been the focus of most historical studies of phenotypic evolution, it has been argued that changes to non-coding cis-regulatory elements may be more important, as they are crucial to the spatiotemporal control of gene expression in development and can change with potentially fewer pleiotropic effects on other processes [4,5]. However, empirical support for this claim is limited, largely by the difficulty of determining the genetic basis of phenotypic changes to a fine enough level to distinguish between cis and protein-coding changes [6]. An additional issue concerns whether the standing genetic variation for phenotypes within populations represent the same spectrum of mutations that go to fixation and become involved in species differences in phenotype [7]. Therefore, additional genetic studies of phenotypic evolution in recently diverged species are needed to help reveal the processes by which new morphologies evolve and the relative roles of cis-regulatory versus protein-coding changes in morphological evolution.

Here we investigate the genetic basis of male-specific differences between two species of *Nasonia*, *N. vitripennis* and *N. giraulti*. *Nasonia* is a complex of four closely related parasitic wasp species that is rapidly emerging as a model for evolutionary and developmental genetics [9,10]. *Nasonia* males are haploid, and therefore can be
Author Summary

The regulation of cell size and cell numbers is an important part of determining the size of organs in development, as well as of controlling cell over-proliferation in diseases such as cancer and diabetes. How the regulation of cell size and number can change to produce different organ sizes is not well understood. Here, we investigate the recent evolution of sex-specific wing size differences between two species that involve changes to cell size and number regulation. Males of the emerging genetic model wasp Nasonia vitripennis have small wings and do not fly, while males of the closely related species N. giraulti have large wings and do fly. We isolated a locus that contributes substantially to this wing size difference by increasing cell size and cell number. Surprisingly, we found that the determinant for this wing size difference is located in the non-coding region between two known transcription factors, the master sex determining gene doublesex and neurogenesis regulator prospero. The mechanism by which ws1 regulates sex specific wing growth has yet to be determined, although differences in dax expression level in developing male wings may indicate a role for this sex determination locus.

Results/Discussion

Sex-specific differences in wing size

Nasonia wings are composed of a larger forewing and smaller hindwing. Here we focus our attention on the forewing, although more subtle differences in the hindwing are also found between the species and sexes. N. giraulti male forewings are 2.16 fold larger in N. vitripennis than in N. giraulti, whereas N. vitripennis males have vestigial wings and do not fly, although they use them in courtship and agonistic displays [16]. A major portion of the male-specific wing-size difference is due to two loci, wing-size1 (ws1) and widewing (wdw) [13,15]. Both ws1 and wdw increase wing size in a sex specific fashion, as seen when introgressed from N. giraulti by backcrossing into N. vitripennis background. In this study, we positionally cloned the ws1 locus to a 13.5 Kb non-coding region, which falls near the sex determination locus. In this study, we positionally clone the when introgressed from N. giraulti and number regulation. Males of the emerging genetic model wasp Nasonia vitripennis have small wings and do not fly, while males of the closely related species N. giraulti have large wings and do fly. We isolated a locus that contributes substantially to this wing size difference by increasing cell size and cell number. Surprisingly, we found that the determinant for this wing size difference is located in the non-coding region between two known transcription factors, the master sex determining gene doublesex and neurogenesis regulator prospero. The mechanism by which ws1 regulates sex specific wing growth has yet to be determined, although differences in dax expression level in developing male wings may indicate a role for this sex determination locus.

Figure 1. Wing size differences due to ws1. Wings of N. giraulti (ws1G), N. vitripennis (ws1V) and giraullti ws1 in vitripennis background (ws1V_40kb). Wing area ± S.D. relative to ws1V males is shown (see also Table 1). Scale bar: 100 μm. doi:10.1371/journal.pgen.1000821.g001

and to more precisely describe its phenotypic effects we (a) reduced the size of the introgressed sequence flanking the ws1 locus to a 40kb segment [see fine-scale mapping and cloning below] and (b) backcrossed the introgressed ws1 segment into a standard N. vitripennis strain (AsymCX) genetic background for >10 generations. This strain is referred to as ws1gV_40kb, and is used to more precisely assess the effects of the ws1 allele on wing size in comparison to the ws1V allele in the same genetic background. Overall male forewing area of ws1gV_40kb is 45% larger than the wild-type ws1V allele (Figure 1; Table 1; Tukey’s HSD test, p<0.001), and the locus accounts for 39% of the species difference in male wing area. Male forewing length and width are similarly increased (Table 1; HSD tests, p>0.05), confirming the sex-specific effects of this locus.

A more detailed analysis of phenotype was conducted using setae (wing cell hairs) to estimate cell size and cell number effects of ws1. Setae have also been used in Drosophila to estimate the relative contribution of cell size and cell number to wing size [e.g., [19]]. In Nasonia, setae cover the distal portion of the wing, but are sparse in the proximal portion (Figure 1). Most of the size increase due to ws1 is in the distal portion of the wing as well (73% increase distal to the costal cell versus 21% increase proximal). We therefore estimated seta densities in the distal portion of the adult wing after first establishing that there was a relationship between cell number and seta number. Cell density per seta in pupal wings was estimated by DAPI and phalloidin staining (Figure S1). The average number of cells per seta in N. vitripennis male forewings is 3.2±0.4 SD, compared to 4.6±0.4 SD in N. giraulti (Mann-Whitney U-test, p<0.05, n = 12). In contrast, the ws1V introgression shows the same density of cells per seta as N. vitripennis (3.2±0.3 SD for each; U-test, p>0.05, n = 12), indicating that this species difference is not under the genetic control of the ws1 locus. We then estimated cell number by counting total seta numbers on the distal portion of the adult wing and estimated cell size by calculating the distance to each seta’s nearest neighbors. Based on these calculations, the ws1 allele increases overall cell size by 21±3% (SD) and cell number by 45±5%, resulting in a
N. longicornis and began in the common ancestor to all four species, with subsequent [15,20]. Thus, we can postulate that either (a) male wing reduction N. giraulti clade [20] that contains both species with intermediate (wings (Figure 1), whereas the other species form a monophyletic ancestral. However, the situation is complicated by the fact that males with large functional wings, suggesting that this state is 73% ± 10% increase in area of the distal half of the wing (Table 2; HSD tests, p<0.05).

It would be useful to know whether large or small male wing-size is ancestral in the Nasonia lineage. Other closely related species (e.g. Trichomalopsis sarcophaga, T. dubia, and Urolepis rufipes) have males with large functional wings, suggesting that this state is ancestral. However, the situation is complicated by the fact that the most basally diverging Nasonia species, N. vitripennis, has small wings (Figure 1), whereas the other species form a monophyletic clade [20] that contains both species with intermediate (N. longicornis) and large winged males (N. giraulti and N. oneida) [15,20]. Thus, we can postulate that either (a) male wing reduction began in the common ancestor to all four species, with subsequent increase in the lineage leading to N. giraulti and N. oneida, (b) smaller male wing size has independently evolved in N. vitripennis and N. longicornis, or (c) there has been introgression of one or more small-wing alleles between N. vitripennis and N. longicornis. Resolution of these alternatives will require more detailed phenotypic and sequence evaluation of the QTL involved in sex specific wing evolution.

### Table 1. Basic wing measurements of ws1 and wild-type strains.

### Table 2. Cell number and size effects of ws1, as estimated by seta number and area.

| Genotype | Seta Number | Seta Area (Nearest 4 Neighbors) | Distal Forewing Area | N (Families) |
|----------|-------------|---------------------------------|----------------------|--------------|
| Males (absolute) |             |                                  |                      |              |
| ws1V     | 580±44      | 117±2                            | 135000±10000         | 8 (2)        |
| Males (relative) |          |                                  |                      |              |
| ws1V     | 1.00±0.08   | 1.00±0.01                        | 1.00±0.07            | 8 (2)        |
| ws1V-40kb | 1.49±0.05   | 1.21±0.03                        | 1.73±0.10            | 8 (2)        |

Seta area and seta number are used to estimate cell size and cell number in the distal portion of the forewing. Seta area is the mean area occupied by each seta, based on the distance to each seta’s nearest four neighbors. Absolute measurements (mean ± standard deviation) are shown for ws1V (N. vitripennis) males (all area units in μm²). Relative measurements are shown as (mean / ws1V mean) ± (standard deviation / ws1V mean). N: number of individuals measured, nested in families.

doi:10.1371/journal.pgen.1000821.t003

Positional cloning of ws1

Positional cloning of the ws1 locus involved the following steps: (a) recessive lethals flanking ws1 were generated using already identified linked visible mutants, (b) these were then used to sequentially generate a set of recombinants on both sides of ws1 for fine-scale mapping and cloning of the gene, (c) a molecular (AFLP) marker tightly linked to ws1 was identified by genotyping recombinants, (d) this marker was then used to identify a set of BACs covering the region, which were assembled into contigs [21], (e) PCR based markers were developed for determining recombination intervals within the region using sequences from the BAC containing the AFLP marker, end sequences of flanking BACs, and corresponding vitripennis and/or giraulti markers (Table S1), (f) a set of increasingly finer-scale recombinants were screened to delineate the ws1 region and finally (g) additional sequence analysis within the cloned region was conducted to identify features within the region and differences between N. vitripennis and N. giraulti. The latter effort was enhanced by the availability of genome sequences for N. vitripennis (Genbank AAZX00000000) and N. giraulti (Genbank ADAO00000000) [10] which became available during the course of this project.

The method of assembly of BAC contigs is described in [21]. The approach for generating linked lethals and using these for cloning of QTL is described in methods and shown in Figure 2. Due to male haploidy, this method can be used to efficiently screen for recessive lethals linked to any gene of interest within the genome. Briefly, new lethal mutations linked to ws1 were generated by EMS mutagenesis followed by screening for linkage of the lethal to ws1. Use of custom-made lethals in this approach was effective because non-recombinant haploid males with the genotype lethal ws1Δ2 die and, therefore, the only surviving males carrying the ws1Δ2 allele are recombinants between the lethal and wing size locus (+ ws1Δ2) (Figure 2). These tightly linked lethals increased the “effective” discovery rate of recombinants within the region by 100–200 fold (Figure 2), greatly enhancing efficiency of the positional cloning effort. Thus, we were able to positionally
clone ws1 despite a 10-fold lower recombination rate in this region, 0.10–0.14 centimorgan/megabase (cM/Mb) relative to the genome-wide average of 1.4–1.5 cM/Mb [22].

We first isolated the giraulti allele of ws1 by backcrossing into a vitripennis background and mapping the locus using visible, lethal and molecular markers (Figure 3A, see also Materials and Methods). Using one line (Rec1, Figure 3C) generated by recombination to the flanking recessive lethal D4, we then generated recombinants on the opposite side between ws1 and the flanking visible marker bl15, resulting in a recombinant line showing the ws1g phenotype with only 40kb of introgressed giraulti sequence. This large-winged recombinant strain [ws1gV_40kb] is used for our detailed phenotypic and gene expression analyses. Screening of additional recombinant genomic DNA controls. The evidence therefore indicates that the ws1g phenotype is due to non-coding DNA within the 13.5kb region.

Investigation of intraspecific variation in the 13.5kb region and approximate 1.5kb and two small “stem loop” regions. contain protein coding sequences, but two inverted repeats of sequence differences occur between giraulti and vitripennis in the 13.5kb ws1 region (Figure 3D), including single-nucleotide polymorphisms (SNPs), insertions/deletions (indels) and the insertion of a foldback transposable element into vitripennis. We sequenced the full foldback element and found that it does not contain protein coding sequences, but two inverted repeats of approximately 1.5kb and two small “stem loop” regions. Investigation of intraspecific variation in the 13.5kb region and ultra-fine scale mapping is now being undertaken to narrow the region that is involved in the ws1 phenotype.

Effects of ws1 on dsx and pros expression

Based on our findings revealing ws1 to contain the 5’ non-coding region of doublesex, we next determined whether this region affects dsx expression. Nasonia doublesex has male and female splice-forms, and experimental evidence supports its role in sex determination in Nasonia [18]. As expected, the male splice-form of dsx (dsxM) is present in developing male wings of vitripennis (ws1gV and ws1gV_40kb (Figure S3). However, quantitative RT-PCR reveals an estimated 2.4X higher level of dsxM transcript in developing preupal male wings of ws1g relative to ws1V in the same vitripennis genetic background (Figure 4; U-test, p = 0.04, n = 7 biological replicates). In contrast, there is no significant difference between the two genotypes in dsxM transcript levels in male legs or whole prepupeae (Figure 4; U-tests, p>0.05, n = 5). We also measured expression of dsx in female wings using non-sex-specific primers and observed no clear difference due to ws1g (median 1.01x expression difference, n = 3; Table 3).

No expression difference was found in male wings for the flanking gene prospero (Table 3; median 1.07x expression difference between ws1V and ws1gV_40kb). We note that while the introgression appeared to have no effect on pros expression in wings, higher pros transcript levels were observed in ws1gV_40kb whole prepupa (Table 3). A likely explanation for this whole-body effect is that the larger 40kb of giraulti sequence in the tested strain extends over part of the pros gene, possibly affecting its regulation in whole body.

These gene expression data provide a sex- and tissue-specific correlation between dsx expression level and wing size. As with other positional cloning studies, our data do not rule out alternative scenarios that could link causative sequence changes in the 13.5kb region to wing size, such as (undetected) effects on prospero or long-distance regulation of a different gene. However, we do note that we started with a sex-specific phenotype and “walked” to a region adjacent to a gene known to be involved in somatic sex determination. Future work will be geared towards sex in a gynandromorph producing line [18]. This previous work on Nasonia dsx [10] confirmed the coding regions, 5′UTR, 3′UTR, exons and introns for both male and female specific splice-forms (shown in Figure S2) in both N. vitripennis and N. giraulti.

Upstream of the ws1 region, the nearest gene was identified by BLAST to be a homolog of the D. melanogaster gene prospero (pros, GenEID 100110692, [10]). 24.5kb away from the ws1 region (Figure 3B). In Drosophila, prospero is a transcription factor that specifies cell fate and cell growth in the nervous system [23]. We also identified a single EST (Genbank EV431998) within the 13.5kb region from the Nasonia EST dataset [10]. The EV431998 EST contains 5-8 stop codons in each frame and is not spliced, and therefore does not appear to be a protein-coding gene. RT-PCR of EV431998 failed to detect this transcript from wing, leg or whole prepupa cDNA, whereas the primers did amplify from genomic DNA controls. The evidence therefore indicates that the ws1 phenotype is due to non-coding DNA within the 13.5kb region.

A number of sequence differences occur between giraulti and vitripennis in the 13.5kb ws1 region (Figure 3D), including single-nucleotide polymorphisms (SNPs), insertions/deletions (indels) and the insertion of a foldback transposable element into vitripennis. We sequenced the full foldback element and found that it does not contain protein coding sequences, but two inverted repeats of approximately 1.5kb and two small “stem loop” regions. Investigation of intraspecific variation in the 13.5kb region and ultra-fine scale mapping is now being undertaken to narrow the region that is involved in the ws1 phenotype.

Table 2. Positional cloning in Nasonia using linked lethals. The diagram illustrates a screen for fine-scale recombinants (marked with *) between ws1g and a lethal located 0.6cM away. Because of the lethal (l), the only live haploid males with ws1g (large wings, w) are recombinant. The blue (b) marker is used as a second phenotypic marker and as a way to identify recombinants on the other side of ws1. Gray bar: introgression (N. giraulti) sequence. White bar: N. vitripennis sequence. Proportions shown are based on estimates of recombination rates between the markers (Figure 3) and assuming no double recombinants.

determining how \textit{ws1} affects sex-specific changes in wing development, and specifically whether changes in \textit{dsx} expression level causally influence male wing size in \textit{Nasonia}.

**Concluding remarks**

Our results show that non-coding changes are responsible for the \textit{ws1} male-specific wing phenotype. Unlike studies of candidate genes involved in sex differentiation, the positional cloning approach is candidate-blind, so it is intriguing that the region we identified as causing a sex specific increase in wing size (\textit{ws1}) also contains the 5\(^{\prime}\) UTR of the sex-signaling gene \textit{doublesex}. Nevertheless a causal relationship between \textit{ws1} and \textit{dsx} has not yet been established. Previous studies [3,24] have implicated \textit{dsx} in the evolution of sex-specific morphology. But rather than changes in \textit{doublesex} itself, these studies revealed changes in downstream targets of \textit{dsx}, via changes to specific DNA sequences to which DSX protein binds in the \textit{cis}-regulatory regions of the \textit{bric-a-brac} and \textit{desatF} genes and affecting sex differences in abdominal pigmentation and pheromone production. In this study, we observed tissue-specific changes in \textit{dsx} level, possibly due to \textit{cis}-regulation. \textit{Dsx} expression level manipulation has been found to affect cell number of a sex-specific cell type in the \textit{Drosophila} brain [25]. If \textit{dsx} is indeed the mechanism behind \textit{ws1}, it would be the second case of \textit{dsx} regulating sex-specific cell proliferation. Further, it would suggest that sex-specific morphology can evolve by

**Figure 4. Change in \textit{doublesex} expression due to \textit{ws1}.** Expression level change was estimated by quantitative RT–PCR. Note that the \textit{vitripennis} \textit{dsx} protein-coding region is present in both genotypes (i.e., the \textit{giraulti} region of \textit{ws1\_V\_40kb} does not include the \textit{dsx} coding sequence). Mean expression ratios \pm standard errors are shown. Expression ratios greater than 1 indicate higher male \textit{dsx} (\textit{dsxM}) transcript level in \textit{ws1\_V} than in \textit{ws1\_V\_40kb}. Sample size indicates number of independent biological replicates. doi:10.1371/journal.pgen.1000821.g004
spatially regulated changes in expression within the sex-determining pathway without disrupting other sex-determination functions. Other molecular mechanisms linking the cloned 13.5kb \textit{ws1} region to wing size evolution could also occur, including \textit{cis}-regulation of \textit{prospero}, changes in non-coding RNAs, or long-distance regulation of another gene. \textit{Propero} is of particular interest because it is a transcription factor known to regulate cell proliferation in the \textit{Drosophila} nervous system [23].

Cell size and cell number regulation are crucial elements of both organ size determination and control of human diseases such as cancer and diabetes [26]. Understanding how growth regulation can evolve therefore has the potential to broaden our knowledge of the operation of these gene networks. One notable example of organ size evolution is \textit{fu2} [2], which regulates tomato fruit size via cell number changes [27]. This gene was positionally cloned [27] and found to be a cell cycle regulator in plants [28]. In \textit{Nasonia}, non-coding \textit{cis}-regulatory evolution at the \textit{ws1} locus causes changes in both cell size and cell number. The two genes flanking the \textit{ws1} region, \textit{doublesex} and \textit{prospero}, have both been found to regulate neuronal cell numbers in \textit{Drosophila}, and \textit{doublesex} does so sex-specifically [23,25]. How a 45% change in organ size might be achieved by either of these genes, each of which has a conserved homologue in the human genome, remains to be determined.

This study demonstrates the feasibility of positional cloning genes in \textit{Nasonia}. A number of biologically important phenotypic differences occur between \textit{Nasonia} species, which are ripe for genetic investigation using this approach, such as wing and antennal morphology [20,29–30], host preference [14], pheromones and cuticular hydrocarbons [31], diapause [32], hybrid incompatibility [33–35], male courtship behavior [36] and female mate preference [20,37]. The four known \textit{Nasonia} species are all inter-fertile in the laboratory, facilitating the isolation of genes involved in complex trait differences between each species [15,30]. The availability of genome sequences [10] combined with the haplodiploid positional cloning methods described here now make it possible to determine the evolution of these complex traits on a molecular level in this emerging model organism [9].

### Materials and Methods

#### Strains used

Wing measurements were conducted using the inbred \textit{N. vitripennis} strain AsymC and inbred \textit{N. giraulti} strain R16A; these data are also reported in [15]. Gene expression experiments were conducted with the \textit{N. vitripennis} AsymCX strain used for genome sequencing [10], which was derived from AsymC by multiple generations of sib-mating. All wing size and gene expression experiments used the minimal-introgression \textit{ws1} strain \textit{ws1gV_40kb}, produced by backcrossing and selection for recombinants between \textit{ws1} and linked visible and lethal mutants (see Positional Cloning below). This strain contains ~40Kb of introgressed \textit{giraulti} DNA containing \textit{ws1} in a \textit{vitripennis} genetic background. It was constructed by backcrossing males from minimal-recombinant strain \textit{wm114} (Rec 4 in Figure 3C) into AsymCX for 10 generations to produce a homogeneous genetic background. Wild-type \textit{N. vitripennis} and \textit{N. giraulti} are also referred to as \textit{ws1} and \textit{ws1G} in the text.

#### Wing size, cell size, and cell number measurements

Wing measurements were performed as in [15]. Briefly, individual females were given two \textit{Sarcophaga bullata} hosts for 48 hours at 25C after host-feeding for 24 hours on two hosts (which were discarded). Male wing samples were collected from the offspring of single virgin females, while female wing samples were collected from the offspring of single mated females. Adult wings were dissected at the hinge adjoining the thorax and dry mounted on microscope slides under coverslips. Five individuals per family for 5–8 families were mounted; occasional damaged or misshapen wings meant that four individuals per family were measured.

Wings were photographed on a Zeiss AxioImager Z1 compound scope at 10X as mosaic images. Measurements were performed on the wing images using AxioVision 4.6 software (Zeiss). Wing length, width, area, and head width (inter-ocular distance, a measure of body size) were measured as in [15]. Briefly, wing length is the distance between a notch at the proximal anterior end of the costal cell and the distal tip of the forewing. Wing width is the distance perpendicular to the length axis between the most anterior and most posterior points on the wing. Wing area is defined by outlining the wing starting at the proximal anterior notch. Measurements of wild-type \textit{N. vitripennis} and \textit{N. giraulti} shown here (Figure 1) are also reported in [15]. Images of \textit{ws1G} and \textit{ws1V} male wings shown in Figure 1 were cropped to remove other mounted wings which appear in frame but are not related to the displayed image.

Setae, hair-like structures produced by cells on the wing blade, were used to infer changes to cell size and number. This approach has been used to estimate cell size in other insects, particularly \textit{Drosophila} [19]. To determine if seta number is a reasonable estimator of cell number in \textit{Nasonia}, the number of cells per seta was determined at the red-orange-eye pupal stage, where setae are most distinguishable before the wing sclerotizes and cell nuclei disappear. Pupal male forewings were clipped and dissected from the cuticle in 1x TBST (6g Tris, 8.76g NaCl, 1mL Tween, 0.2g NaN3, 1L H2O, pH 7.5) then fixed on lyse-coated slides in 3.7% formaldehyde. Slides were stained with DAPI and Alexa Fluro488-Phalloidin (Invitrogen, Carlsbad, CA, USA) and mounted in ProLong Gold (Invitrogen). The wing is not completely expanded at this stage and has some three-dimensional structure (Figure S1). Therefore, wings were imaged at 20X as mosaics under multiple focal planes, so that setae on both wing surfaces and all nuclei could be detected. All setae and nuclei were then counted within a

Positional cloning methods

Positional cloning efforts were begun by identifying visible mutants linked to \textit{ws1}. Using the original \textit{ws1} introgression from \textit{giraulti} into \textit{vitrupennis} (INT\textsubscript{w1.1}, [13]), it was ascertained that the visible eye color mutant or123 and body color mutant bl13 map near to \textit{ws1}. A second introgression of \textit{ws1} into \textit{vitrupennis} containing a large \textit{giraulti} flanking region was used for most of the fine-scale mapping and positional cloning work (strain INT\textsubscript{bkbw}, described in [14]). This introgression contains a naturally occurring \textit{giraulti} black eye color allele, \textit{bkbw}, linked to \textit{ws1}. We found that \textit{bkbw} fails to complement the \textit{N. vitripennis} mutant \textit{bk}576 in heterozygous females. \textit{bkbw} produces oyster-gray eyes in the \textit{pe333} (peach eye) mutant background, which is easier to see than the black eyes of the mutant in wild-type background. A recombination map of these visible markers is shown in Figure 3A.

To further assist in the positional cloning, recessive lethal mutations linked to \textit{ws1} were generated in the INT\textsubscript{bkbw} strain by ethyl methanesulfonate (EMS) treatment of males carrying \textit{ws1}. Ten \textit{bkbw} \textit{(ws1\textsubscript{L}, \textit{bkbw}; \textit{pe333})} males were placed in 25mm Drosophila vials containing filter paper soaked 10% sucrose solution containing 0.25-0.5% EMS (Sigma Chemical). After 7–10h, males were transferred to a vial containing clean filter paper overnight. Mutagenized males were then crossed to \textit{virgins} and the F1 progeny were screened for \textit{ws1} and \textit{bkbw}. F1 Virgin females were collected, transferred to individual cells of plastic 24-well culture plates (Medison) and each fly host to lay eggs. Plates were sealed with a double layer of Micropore tape (product number 1530-03, 3M Corporation) and incubated at 25C. After 48h, females were transferred to a new plate containing a \textit{pe333} male black-stage pupa and a spot of honey water. After mating, the wasps were anesthetized at 4C and on ice, 2 fly hosts were added to each well, and then incubated at 21C. Newly-created linked recessive lethal markers were identified by distortions in F2 ratios of the visible markers \textit{(ws1\textsubscript{L}, \textit{bkbw}; \textit{pe333})} among the haploid F2 males of the virgin hosting (as in Figure 2) and then linkage relationships were determined. Lethal lines were maintained using heterozygous female offspring. One lethal line, \textit{lethal}\textsuperscript{d4}, was primarily used for mapping in this study, due to its close linkage to \textit{ws1} and its position on the side opposite the visible markers (Figure 3A).

To collect recombinant males for positional cloning, females heterozygous for \textit{ws1\textsubscript{L}} and a flanking visible or lethal marker were set as \textit{virgins} and resulting haploid male progeny were screened for recombination between the marker locus and \textit{ws1} by phenotype (Figure 2). Use of lethals in this approach was especially effective because non-recombinant haploid \textit{lethal} \textit{ws1\textsubscript{L}} males die; the only surviving males carrying the \textit{ws1\textsubscript{L}} allele were recombinants between the lethal and wing size locus. Penetration of the lethal genes used was found to be 100%. These tightly linked markers increased the “effective” discovery rate of recombinants within the region by 100–200 fold, greatly enhancing efficiency of the positional cloning efforts.

A crucial step in the cloning effort was identification of molecular markers within the \textit{ws1} region to assist in fine-scale recombinant mapping. Initially this was accomplished by screening the original \textit{ws1\textsubscript{L}} introgression line and recombinants between it and flanking visible markers for linked Amplified Fragment Length Polymorphism (AFLP) markers. This was done using methods previously reported in [39]. A marker termed “AF1” was identified and found to be tightly linked to \textit{ws1}. The marker was cloned and sequenced. PCR products from primers designed to AF1 were used to screen a BAC library to \textit{N. vitripennis}. Ends of a subset of BACs were sequenced, the library re-screened, and then AFLP typed to assemble a set of BACs [21]. BAC-end sequences were then used to generate a set of molecular markers distinguishing \textit{vitripennis} and \textit{giraulti} by PCR and AFLP (Table S1; [21]). Subsequent sequencing of a \textit{giraulti} BAC (Genbank accession AC185390) which included the entire \textit{ws1\textsubscript{L}} region and alignment of \textit{vitripennis} and \textit{giraulti} trace reads from the \textit{Nasonia} genome project were used to identify additional PCR markers for ultra fine-scale mapping, and identification of recombination breakpoints by sequencing. Genotyping primers and PCR conditions are shown in Table S1.

Over 2000 recombinant haploid males were identified between \textit{ws1} and either the visible or lethal marker. These were screened with molecular markers to identify the location of recombination within the region around \textit{ws1}. The most informative recombinants are shown in Figure 3C. These include recombinants produced from the INT\textsubscript{w1.1} introgression (Rec 5) and the INT\textsubscript{bkbw} introgression (Recs 1–4, 6–7). To define the \textit{ws1} region further, a strain was established from a recombinant between the flanking \textit{lethal}\textsuperscript{d4} and \textit{ws1} that contained a relatively small region of \textit{giraulti} introgression but retained the large wing phenotype (Rec1 in Figure 3C). This strain was used for subsequent recombination to the other flanking region (\textit{bl13} side). A recombinant from this second set containing only 40kb of \textit{giraulti} sequence (Rec4, Figure 3C) yet still showing the “\textit{ws1}” large-wing phenotype (Figure 1) was then backcrossed into the genome-sequenced AsymCX strain for >10 generations, and then purebred. This strain (called \textit{ws1\textsubscript{L}, 40kb}) was used for wing measurements and quantitative PCR. Additional recombinants from these experiments further localized the \textit{ws1} effect to a 10.8kb region in \textit{giraulti}, and a corresponding 13.5kb in \textit{vitripennis} due to insertion/deletion differences. We examined this sequence and flanking regions for gene predictions [10] and also manually scanned the region for open reading frames and ESTs [18]. The region does not contain protein coding sequence for \textit{dsx}, but only the \textit{dsx} 5’ UTR, promoter and cis-regulatory region.

Recombination rate

We estimated the recombination rate between \textit{ws1} and \textit{lethal}\textsuperscript{d4} by counting all (living) male offspring of a set of virgin females (\textit{lethal}\textsuperscript{d4} \textit{ws1\textsubscript{L}/+}) hosted for positional cloning, 89 males out of
15594 screened were recombinant (+ *ws1*), a map distance of 0.57cM. Of a larger set of 683 + *ws1* recombinant males screened with the ws1–8 marker (Table S1), 6 were recombinant between ws1–8 and *ws1*, a distance of 36–50kb (uncertainty is due to the uncertainty in the location of *ws1* in the 13.5kb region). Local recombination rate was calculated as [0.57 cM between ws1 and *lethalD4*] / (683 recombinants between ws1 and *lethalD4*) = (6 recombinants between ws1 and ws1–8) / (36 or 50kb between ws1 and ws1–8) = 0.14 – 0.10 cM/Mb.

RT–PCR and quantitative RT–PCR

RNA was isolated from wing discs, leg discs and whole individuals at the third instar larvae - prepupal transition. We found that this stage can be precisely identified to a few hours, between defecation of the larvae and ecdysis. Wing and leg discs were dissected from post-defecation prepupae under RNase free conditions in 1X phosphate-buffered saline. After dissection, tissues were placed immediately on ice and if necessary stored at −80°C until RNA was isolated. Independent extractions of tissue were conducted to produce independent biological replicates. Each biological replicate consisted of 15–30 prepupal wings or legs or a single whole prepupa of each genotype (ws1, V and ws1, V = 40kb). Total RNA was isolated using Trizol (Invitrogen). RNA was then quantified using a Qubit fluorometer (Invitrogen) and a Quant-iT RNA Assay Kit (Invitrogen) or a ND-1000 Spectrophotometer (NanodropTechnologies, Oxfordshire, UK). Expression of EV431998 was tested in RT-PCR with primers TCGAGTCCTGGAAAGTAGCCAT and AATACCTGAACTTTTGACGATAAGCAC. RT-PCR of other genes (dsx, rp49 and pros) was amplified using primers GCGGATGTGGAAGTGTTCTTCTGGGTGAG and CCAGGAAGTTAGGACTCAGCCAAACCGTTGTAAT. All steps were performed according to the reaction conditions are presented in [18].

For quantitative RT-PCR, first-strand cDNA Synthesis and qPCR were performed using SuperScript™ III Platinum SYBR Green Two-Step qRT-PCR Kit with ROX (Invitrogen) on an Applied Biosystems 7300 Real Time PCR System. RNA samples were split into reverse-transcribed and -RT controls. Male specific (dsx = dsxM), was amplified using primers CGGAGGTGTGGAGTAGCCAT and AATACCTGAACTTTTGACGATAAGCAC. Reaction was performed by examining multiple focal planes to track setae and nuclei across different depths. The figure shows single focal planes for setae and for nuclei. (A–C) Setae from pupal male forewings. (D–F) Nuclei from pupal male forewings. (G–I) Closeups of seta from adult male forewings (G–I) show changes in seta density (which estimate cell size). All images are from the distal portion of the forewing of *ws1*, *V* (A,D), *ws1, V* (B,E,H) and *ws1, F* (C,F,I). Pupal setae and nuclei images (e.g., A,D) are different fluorescence channels from the same image (coincident, but from different focal planes). Levels were adjusted uniformly for each panel to improve visual contrast. Scale bar for (A–G): 10 μm. Scale bar for (G–I): 10 μm.

Figure S2 Locations of *dsx* primers. Primer locations used for RT-PCR and qPCR of *dsx* are shown in relation to the *dsx* gene model. Male and female splice-forms are adapted from [18]. Lengths are not to scale. Approximate primer locations (half-arrows) are shown on the male splice-form for (a) male-specific dsxM qPCR, (b) non-sex-specific dsx qPCR, and (c) dsx RT-PCR. Presence of unspliced dsx product in females is expected [18]. (A) (i, ii) Standard RT-PCR. Lanes 1,2: *ws1, V* male prepupal wing cDNA. Lanes 3,4: *ws1, V* male prepupal leg cDNA. Lanes 5: *ws1, V* female prepupal wing cDNA. Lane 6: *ws1, V* female prepupal leg cDNA. Lane 7: *ws1, V* female whole pupal cDNA included for reference. (Aii) Lane 8: no-template control (image from a separate row of same gel). 1kb: 1 kilobase DNA ladder (Invitrogen). (B) RT-PCR using concentrated cDNA. Specifically, *ws1, V* 40kb male prepupal wing cDNA. Lane 6: *ws1, V* 40kb male prepupal leg cDNA. Lane 7: *ws1, V* female whole pupal cDNA included for reference. (Aii) Lane 8: no-template control (image from a separate row of same gel). 1kb: 1 kilobase DNA ladder (Invitrogen). (B) RT-PCR using concentrated cDNA. Specifically, *ws1, V* 40kb male prepupal wing cDNA. Lane 6: *ws1, V* 40kb male prepupal leg cDNA. Lane 7: *ws1, V* female whole pupal cDNA included for reference. (Aii) Lane 8: no-template control (image from a separate row of same gel). 1kb: 1 kilobase DNA ladder (Invitrogen). (B) RT-PCR using concentrated cDNA. Specifically, *ws1, V* 40kb male prepupal wing cDNA. Lane 6: *ws1, V* 40kb male prepupal leg cDNA. Lane 7: *ws1, V* female whole pupal cDNA included for reference. (Aii) Lane 8: no-template control (image from a separate row of same gel). 1kb: 1 kilobase DNA ladder (Invitrogen).

Figure S3 *dsx* splicing in male prepupal wings. RT-PCR of the differentially spliced 3’ domain of *dsx* in prepupal male wings is shown. RNA from single male prepupal wings, single male prepupal legs, and single whole pupal females was isolated using the Dynabeads mRNA DIRECT Micro Kit (Invitrogen) by the mini volumes protocol. Black arrowhead: 573bp unspliced (male) product. White arrowhead: 463bp spliced (female) product.

Supporting Information

Figure S1 Wing setae are used to estimate changes in cell size. Example images of seta and nuclear density from male pupal and adult forewings are shown. Adult wing seta numbers and densities were used to infer changes in cell number and cell size due to *ws1* (Table S2), based on estimates of the number of cells (nuclei) per seta in the pupal wing (Data presented in main text). Precise counts were performed by examining multiple focal planes to track setae and nuclei across different depths. The figure shows single focal planes for setae and for nuclei. (A–C) Setae from pupal male forewings. (D–F) Nuclei from pupal male forewings. (G–I) Closeups of seta from adult male forewings (G–I) show changes in seta density (which estimate cell size). All images are from the distal portion of the forewing of *ws1*, *V* (A,D), *ws1, V* (B,E,H) and *ws1, F* (C,F,I). Pupal setae and nuclei images (e.g., A,D) are different fluorescence channels from the same image (coincident, but from different focal planes). Levels were adjusted uniformly for each panel to improve visual contrast. Scale bar for (A–G): 10 μm. Scale bar for (G–I): 10 μm.

Table S1 Primers used to genotype recombinants in the *ws1* region. Base pair position in *N. vitripennis* genome assembly v1.0 SCAFFOLD23 is shown. Dashed line denotes markers within the mapped 13.5kb/10.8kb *ws1* region. PCR conditions for all markers: 94C for 2min, 34 cycles of (94C for 30s, 55C for 45s, 72C for 60s), 72C for 10min. Enzyme: Restriction enzyme used to distinguish the amplicons of the two species-genotypes. Assays marked with “indel” did not require enzymes to distinguish the species-genotype; “sequence” requires sequencing of the PCR product.

Acknowledgments

We are grateful to J. Romero-Severson for developing the *N. vitripennis* BAC library; Stephen Richards and the Baylor Human Genome Sequencing center for sequencing of BAC clones as part of the *Nasonia* genome project; Rhitoban Raychoudhury, Jen Traggis, Laramy Enders, and Adityarup Chakravorty for assistance with laboratory work; Heinrich Jasper for advice on qPCR; and Claude Desplan for comments on the manuscript.
