I. INTRODUCTION

The inflationary paradigm has become a cornerstone of modern cosmology. As measurements of the Cosmic Microwave Background (CMB) radiation grow increasingly precise, it has become topical to look beyond the simplest single-field, slow-roll inflationary scenario. In particular, it is interesting to determine the extent to which non-minimal signatures, such as features in the primordial power spectrum or observable nongaussianities, can be accommodated by microscopically sensible inflation models. Efforts in this direction are valuable because they allow us to test our theoretical prejudices and provide observers with well-motivated templates for departures from the standard scenario. Finally, a detection of some non-minimal features might open a rare observational window into fundamental particle physics at extremely high energy scales. In this work, we will consider a very simple and well-motivated class of models which predict novel observable signatures in the spectrum and bispectrum of the primordial curvature fluctuations.

In a variety of inflation models, the motion of the inflaton can trigger the production of some non-inflaton (iso-curvature) particle during inflation. Models of this type have attracted considerable interest recently; examples have been studied where particle production occurs via parametric resonance [10–17], or otherwise [18]. Such constructions are novel for a variety of reasons:

1. The produced iso-inflaton particles may rescatter off the slow-roll condensate and generate a significant contribution to the primordial curvature fluctuations through the process of Infra-Red (IR) cascading [1]. This provides a new mechanism for generating cosmological perturbations that is qualitatively different from the standard mechanism [19], the curvaton [20, 21] or modulated fluctuations [22, 23].

2. Particle production and IR cascading leads to a variety of novel observational signatures, including features in the primordial power spectrum and also nongaussianities [1, 2].

3. Particle production arises naturally in a number of microscopically realistic models of inflation, including examples from string theory [3] and supersymmetric (SUSY) field theory [22]. In particular, inflationary particle production is a generic feature of open string inflation models [2], such as brane/axion monodromy [28–31]. (See also [32].)

4. Observable features in the primordial power spectrum, generated by particle production and IR cascading, offer a novel example of the non-decoupling of high scale physics in the Cosmic Microwave Background (CMB) [4, 35]. In the most interesting examples, the produced particles are extremely massive for (almost) the entire history of the universe, however, their effect cannot be integrated out due to the non-adiabatic time dependence of the iso-inflaton mode functions during particle production. In [4] particle production during large field inflation was proposed as a possible probe of Planck-scale physics.

5. The energetic cost of producing particles during inflation has a dissipative effect on the dynamics of the inflaton. Particle production may therefore...
slow the motion of the inflaton, even on a steep potential. This gives rise to a new inflationary mechanism, called \textit{trapped inflation} \[3, 32\], which may circumvent some of the fine tuning problems associated with standard slow-roll inflation. See \[3\] for an explicit string theory realization of trapped inflation and \[34\] for a generalization to higher dimensional moduli spaces and enhanced symmetry loci.

The idea of using dissipative dynamics to slow the motion of the inflaton was exploited also for a very interesting mechanism (which pre-dates trapped inflation) called \textit{warm inflation} \[24, 27\]. See also the variant of natural inflation \[35\] that was proposed recently by Anber & Sorbo \[18\].

In this article we study the impact of isolated bursts of inflationary particle production on the observable primordial curvature perturbations. In order to illustrate the basic physics, we focus on a very simple and general prototype model where the inflaton, $\phi$, and iso-inflaton, $\chi$, fields interact via the coupling

$$\mathcal{L}_{\text{int}} = -\frac{g^2}{2} (\phi - \phi_0)^2 \chi^2$$

(1)

On physical grounds, we expect that our results will generalize in a straightforward way to more complicated models, such as fermion iso-inflaton fields, gauged interactions and (perhaps) inflationary phase transitions.

Scalar field interactions of the type \[1\] have also been studied recently in connection with non-equilibrium Quantum Field Theory (QFT) \[37\], in particular with applications to the theory of preheating after inflation \[41–46\] and also moduli trapping \[33, 34\] at enhanced symmetry points. Although our focus is on particle production \textit{during} inflation (as opposed to during preheating, after inflation) some of our results nevertheless have implications for preheating, moduli trapping and also non-equilibrium QFT more generally. For example, in \[1\] analytical and numerical studies of rescattering and IR cascading during inflation made it possible to observe, for the first time, the dynamical approach to the turbulent scaling regime that was discovered in \[47, 48\].

Let us now discuss briefly the physics of the model \[1\]. At the moment when $\phi = \phi_0$ (which we assume occurs during the observable range of $e$-foldings of inflation) the $\chi$ particles become instantaneously massless and are produced by quantum effects. This burst of particle production drains energy from the condensate $\phi(t)$, temporarily slowing the motion of the inflaton background and violating slow roll. Shortly after this moment the $\chi$ particles become extremely non-relativistic, so that their number density dilutes as $a^{-3}$, and eventually the inflaton settles back onto the slow roll trajectory.

The dominant effect of particle production on the observable spectrum of curvature fluctuations arises because the produced, massive $\chi$ particles can rescatter off the condensate to generate bremsstrahlung radiation of long-wavelength $\delta\phi$ fluctuations via diagrams such as Fig. 1. Multiple such rescatterings lead to a rapid cascade of power into the IR. The inflaton modes generated by this IR cascading freeze once their wavelength crosses the horizon and lead to a bump-like feature in the primordial power spectrum. This bump-like feature is accompanied by a localized, uncorrelated nongaussian feature in the bispectrum \[1\].

In this paper we extend previous work \[1, 2\] on the model \[1\]. First, we re-visit the problem of quantifying the magnitude of the produced nongaussianity. Using lattice field theory simulations we compute numerically the skewness and kurtosis of the Probability Distribution Function (PDF) of the primordial curvature fluctuations. By comparison to the more familiar local model of nongaussianity, we argue that the bispectrum associated with this mechanism may be observable in future missions.

Next, we provide a detailed analytical theory of the quantum production of $\chi$ particles and the subsequent rescattering off the slow-roll condensate for the model \[1\]. This new formalism improves significantly upon previous efforts \[1\] by consistently incorporating both the expansion of the universe and also metric perturbations. We test our approach by comparison to fully nonlinear lattice field theory simulations, finding excellent agreement. We also use our formalism to estimate the shape of the bispectrum.

The outline of this paper is as follows. In section \[II\] we review the key results of \[1, 2\], describing heuristically the underlying mechanism of IR cascading and the resultant observational signatures. In section \[III\] we characterize the size of the nongaussianity associated with particle production and IR cascading, relying primarily on lattice field theory simulations. In section \[IV\] we provide an analytical theory of inflationary particle production and IR cascading in the model \[1\], neglecting metric perturbations. Using this new formalism we estimate the shape
of the bispectrum in the model (I). In section [V] we reconsider our analytical approach, showing how metric perturbations can be consistently incorporated and, further, we demonstrate explicitly that their inclusion does not significantly alter the results of section [IV]. Finally, in section [VI] we conclude.

II. OVERVIEW OF THE MECHANISM

In this section we provide a brief overview of the dynamics of particle production and IR cascading in the model (I) and we also summarize the key observational signatures. This section is largely review of [1, 2], the reader already familiar with those works may wish to skip ahead to the next section.

We consider the following model

\[
S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R - \frac{1}{2} (\partial \phi)^2 - V(\phi) \right. \\
\left. - \frac{1}{2} (\partial \chi)^2 - \frac{g^2}{2} (\phi - \phi_0)^2 \chi^2 \right] \tag{2}
\]

where \( R \) is the Ricci curvature constructed from the metric \( g_{\mu\nu} \), \( \phi \) is the inflaton field and \( \chi \) is the iso-inflaton. As usual, we assume a flat FRW space-time with scale factor \( a(t) \)

\[
ds^2 = g_{\mu\nu} dx^\mu dx^\nu = -dt^2 + a^2(t) d\mathbf{x}^2 \tag{3}
\]

and employ the reduced Planck mass \( M_p \equiv (8\pi G_N)^{-1/2} \approx 2.43 \times 10^{18} \text{ GeV} \). We leave the potential \( V(\phi) \) driving inflation unspecified except to assume that it is sufficiently flat in the usual sense; that is \( \epsilon \ll 1, |\eta| \ll 1 \) where

\[
\epsilon \equiv \frac{M_p^2}{2} \left( \frac{V'}{V} \right)^2, \quad \eta \equiv M_p^2 \frac{V''}{V} \tag{4}
\]

are the usual slow roll parameters.

The coupling \( \frac{g^2}{2} (\phi - \phi_0)^2 \chi^2 \) is introduced to ensure that the iso-inflaton field can become instantaneously massless at some point \( \phi = \phi_0 \) along the inflaton trajectory (which we assume occurs during the observable range of \( \epsilon \)-foldings of inflation). At this moment \( \chi \) particles will be produced by quantum effects. (In section [IV] we will discuss how particle production and rescattering are modified by the inclusion of a mass term \( \mu^2 \chi^2 \) for the iso-inflaton.)

A. Quantum Production of \( \chi \) Particles

Let us first consider the homogeneous dynamics of the inflaton field, \( \phi(t) \). Near the point \( \phi = \phi_0 \) we can generically expand

\[
\phi(t) \approx \phi_0 + vt \tag{5}
\]

where \( v = \dot{\phi}(0) \) and we have arbitrarily set the origin of time so that \( t = 0 \) corresponds to the moment when \( \phi = \phi_0 \). The interaction (I) induces an effective (time varying) mass for the \( \chi \) particles of the form

\[
m_\chi^2 = g^2 (\phi - \phi_0)^2 \approx k_\chi^4 t^2 \tag{6}
\]

where we have defined the characteristic scale

\[
k_* = \sqrt{|g|} \tag{7}
\]

It is straightforward to verify that the simple expression (6) will be a good approximation for \( |H(t)|^{-1} \lesssim \mathcal{O}(\epsilon, \eta) \) which, in most models, will be true for the entire observable 60 \( \epsilon \)-foldings of inflation.

Note that, without needing to specify the background inflationary potential \( V(\phi) \), we can write the ratio \( k_/ H \) as

\[
k_* = \sqrt{g} \tag{8}
\]

where \( P_{\zeta}^{1/2} = 5 \times 10^{-5} \) is the usual amplitude of the vacuum fluctuations from inflation. In this work we assume \( k_* > H \) which is easily satisfied for reasonable values of the coupling \( g^2 > \times 10^{-7} \). In particular, for \( g^2 \sim 0.1 \) we have \( k_/ H \sim 30 \).

The scenario we have in mind is the following. Inflation starts at some field value \( \phi > \phi_0 \) and the inflaton rolls toward the point \( \phi = \phi_0 \). Initially, the iso-inflaton field is extremely massive \( m_\chi \gg H \) and hence it stays pinned in the vacuum, \( \chi = 0 \), and does not contribute to super-horizon curvature fluctuations. Eventually, at \( t = 0 \), the inflaton rolls through the point \( \phi = \phi_0 \) where \( m_\chi = 0 \) and \( \chi \) particles are produced. To describe this burst of particle production one must solve the following equation for the \( \chi \)-particle mode functions in an expanding universe

\[
\ddot{\chi}_k + 3H \dot{\chi}_k + \left[ \frac{k^2}{a^2} + k_\chi^4 t^2 \right] \chi_k = 0 \tag{9}
\]

Equations of this type are well-studied in the context of preheating after inflation [42] and moduli trapping [33]. In the regime \( k_/ > H \) particle production is fast compared to the expansion time\(^1\) and one can solve (9) very accurately for the occupation number of the created \( \chi \) particles

\[
n_k = e^{-\pi k^2 / k_*^2} \tag{10}
\]

\(^1\) In the opposite regime, \( k_* \ll H \), the field \( \chi \) will be light as compared to the Hubble scale for a significant portion of inflation. In this case it is no longer consistent to treat the background dynamics as being effectively single-field, hence the scenario has changed considerably. We will not consider this possibility any further.
Very quickly after the moment $t = 0$, within a time $\Delta t \sim k_{\star}^{-1} \ll H^{-1}$, these produced $\chi$ particles become non-relativistic ($n_\chi > H$) and their number density starts to dilute as $a^{-3}$.

Following the initial burst of particle production there are two distinct physical effects which take place. First, the energetic cost of producing the gas of massive out-of-equilibrium $\chi$ particles drains energy from the inflaton condensate, forcing $\dot{\phi}$ to drop abruptly. This velocity dip is the result of the backreaction of the $\chi$ fluctuations on homogeneous condensate $\phi(t)$. The second physical effect is that the produced massive $\chi$ particles rescatter off the condensate via the diagram Fig. 1 and emit bremsstrahlung radiation of light inflaton fluctuations (particles). Backreaction and rescattering leave distinct imprints in the observable cosmological perturbations. Let us discuss each separately.

B. Backreaction Effects

We first consider the impact of backreaction. This effect can be studied analytically using the mean field equation

$$\ddot{\phi} + 3H \dot{\phi} + V,\phi + g^2 (\phi - \phi_0) \langle \chi^2 \rangle = 0 \quad (11)$$

where the vacuum average is computed following \[33, 42\]

$$\langle \chi^2 \rangle \equiv \Theta(t) \frac{n_\chi a^{-3}}{g|\phi - \phi_0|} \quad (12)$$

and $n_\chi = \int \frac{d^3k}{(2\pi)^3} n_k \sim k_{\star}^3$ is the total number density of produced $\chi$ particles. The Heaviside function $\Theta(t)$ in \[12\] enforces the fact that the backreaction effects become important only for $t > 0$, after the $\chi$ particles have been produced. The factor of $a^{-3}$ in \[12\] reflects the usual volume dilution of non-relativistic matter.

The solutions of \[11\] display the expected behaviour: the energetic cost of the production of $\chi$ particles at $t = 0$ leads to an abrupt dip in the velocity $\dot{\phi}$, momentarily violating the smallness of the slow roll parameter $\dot{\phi}/(H\dot{\phi})$. Within a few $e$-foldings of the moments $t = 0$, the produced $\chi$ particles have become extremely massive and have been diluted away by the inflationary expansion of the universe. At this time, the inflaton must settle back onto the slow roll trajectory, $\phi \cong -V'/(3H)$.

Backreaction effects lead to a transient violation of slow roll, and hence we expect an associated “ringing” pattern (damped oscillations) in the primordial curvature fluctuations, similar to models with a sharp feature in the potential \[14, 16, 49, 54\]. This effect can be seen by solving the well-known equation for the curvature perturbation on co-moving hypersurfaces, $R$, in linear theory:

$$R'' + 2\frac{c'}{z} R' + k^2 R = 0 \quad (13)$$

Here the prime denotes derivatives with respect to conformal time $\tau = \int^t a^{-1}(t')dt'$ and $z \equiv a\dot{\phi}/H$. Note that \[13\] is valid only in the absence of entropy perturbations. However, in our case the $\chi$ field is extremely massive, $m_\chi^2 \gg H^2$, for nearly the entire duration of inflation, hence the direct iso-curvature contribution to $R$ is negligible.

In \[1\] the coupled system \[11, 13\] was solved numerically and the expected ringing pattern in the power spectrum $P_R(k) = \frac{k^3}{8\pi^2} |\mathcal{R}_k|^2$ was obtained. (See also \[2\].) This effect is sub-dominant to the rescattering processes described in the next subsection, hence we will not pursue backreaction any further in this work.

C. Rescattering Effects

The second physical effect which takes place after the quantum production of $\chi$ particles in the model \[1\] is rescattering. This effect was considered for the first time in the context of inflationary particle production in \[3\]. Fig. \[1\] illustrates the dominant process: bremsstrahlung emission of long-wavelength $\delta \phi$ fluctuations from rescattering of the produced $\chi$ particles off the condensate $\phi(t)$. The time scale for such processes is set by the microscopic scale, $k_{\star}^{-1}$, and is thus very short compared to the expansion time, $H^{-1}$. Moreover, the production of inflaton fluctuations $\delta \phi$ deep in the IR is extremely energetically inexpensive, since the inflaton is very nearly massless. The combination of the short time scale for rescattering and the energetic cheapness of radiating IR $\delta \phi$ leads to a rapid build-up of power in long wavelength inflaton modes: IR cascading. This effect leads to a bump-like feature in the power spectrum of inflaton fluctuations, very different from the ringing pattern associated with backreaction. The bump-like feature from rescattering dominates over the ringing pattern from backreaction for all values of parameters.

In \[1\] the model \[2\] was studied using lattice field theory simulations, without neglecting any physical processes (that is to say that full nonlinear structure of the theory, including backreaction and rescattering effects, was accounted for consistently). However, this same dynamics can be understood analytically by solving the equation for the inflaton fluctuations $\delta \phi$ in the approximation that all interactions are neglected, except for the diagram Fig. 1. The appropriate equation is

$$\delta \ddot{\phi} + 3H \delta \dot{\phi} - \frac{\nabla^2}{a^2} \delta \phi + V,\phi \delta \phi \equiv -g^2 [\phi(t) - \phi_0] \chi^2 \quad (14)$$

The solution of \[14\] may be split into two parts: the solution of the homogeneous equation and the particular solution which is due to the source term. Schematically we have

$$\delta \phi(t, x) = \delta \phi_{vac}(t, x) + \delta \phi_{resc}(t, x) \quad (15)$$

The former contribution is the homogeneous solution which behaves as $\delta \phi_{vac} \sim H/(2\pi)$ on large scales and,
physically, corresponds to the usual scale invariant vacuum fluctuations from inflation. The particular solution, \( \delta \phi_{\text{resc}} \), corresponds physically to inflaton fluctuations which are generated by rescattering. The abrupt growth of \( \chi \) inhomogeneities at \( t = 0 \) sources the particular solution \( \delta \phi_{\text{resc}} \), leading to the production of inflation fluctuations which subsequently cross the horizon and become frozen.

A detailed analytical theory of equation (14) will be the subject of sections [14] and [15]. Here we simply point out that the primordial power spectrum in the model [11] may, to good approximation, be described by a simple semi-analytic fitting function [2]

\[
P_R(k) = A_s \left( \frac{k}{k_0} \right)^{n_s - 1} + A_{\text{IR}} \left( \frac{\pi e}{3} \right)^{3/2} \left( \frac{k}{k_{\text{IR}}} \right)^3 e^{-\frac{2}{3} \left( \frac{k}{k_{\text{IR}}} \right)^2} \tag{16}
\]

where the first term corresponds to the usual vacuum fluctuations from inflation (with amplitude \( A_s \) and spectral index \( n_s \)) while the second term corresponds to the bump-like feature from particle production and IR cascading. The amplitude of this feature (\( A_{\text{IR}} \)) depends on \( g^2 \), while the location (\( k_{\text{IR}} \)) depends on \( \phi_0 \).

In [2] the simple fitting function (16) was used to place observational constraints on inflationary particle production using a variety of cosmological data sets. Current data are consistent with rather large spectral distortions of the type (16). Features as large as \( A_{\text{IR}}/A_s \sim 0.1 \) are allowed in the case that \( k_{\text{IR}} \) falls within the range of scales relevant for CMB experiments. A feature of this magnitude corresponds to a realistic coupling \( g^2 \sim 0.01 \). Even larger values of \( g^2 \) are allowed if the feature is localized on smaller scales. In [52] Large Scale Structure forecast constraints were considered for the model (16). It was shown that, for \( k_{\text{IR}} \lesssim 0.1 \) Mpc \(^{-1} \), the constraint on \( A_{\text{IR}}/A_s \) will be strengthened to the 0.5% level by Planck or 0.1% including also data from a Square Kilometer Array (SKA). With a Cosmic Inflation Probe (CIP) similar constraints could be achieved for \( k_{\text{IR}} \) as large as 1 Mpc \(^{-1} \).

### D. Nongaussianity from Particle Production

The bump-like feature in \( P(k) \), corresponding to the second term in (16), must be associated with a nongaussian feature in the bispectrum [1]. Indeed, it is evident already from inspection of equation (14) that the inflaton fluctuations generated by rescattering are significantly nongaussian; the particular solution of (14) is bi-linear in the gaussian field \( \chi \).

Nongaussian statistics have attracted a considerable amount of interest recently, owing to their potential as a tool for observationally discriminating between the plethora of inflationary models in the literature. Although the simplest single-field slow roll models are known to produce negligible (primordial) nongaussianity [56–58], there are a currently a number of alternative models which may predict an observable signature. Examples include models with preheating into light fields [1], [52, 61], nonlocal inflation [62], the curvaton mechanism [63], multi-field models [64], constructions with a small sound speed [65] (such as DBI [66] inflation), trapped inflation [2], the gelaton [67], models with features or rapid oscillations in the inflaton potential [51, 52], non-vacuum initial conditions [65, 68–70], warm inflation [71], etc.

Nongaussianity is usually characterized in terms of the bispectrum, \( B_\zeta(k_i) \), which is the 3-point correlation function of the Fourier transform of the primordial curvature fluctuation on uniform density hypersurfaces, \( \zeta \). Explicitly, we define

\[
\langle \zeta_{k_1} \zeta_{k_2} \zeta_{k_3} \rangle = (2\pi)^3 \delta^{(3)}(k_1 + k_2 + k_3)B_\zeta(k_i) \tag{17}
\]

where \( k_i \equiv |k_i| \) and \( \zeta \), is related to the variable \( R_k \) appearing in (13) as \( \zeta \equiv -R_k \) on large scales \( k \ll aH \). The delta function in (17) reflects translational invariance and ensures that \( B_\zeta(k_i) \) depends on three wavenumbers which form a triangle: \( k_1 + k_2 + k_3 = 0 \). A general bispectrum \( B_\zeta(k_i) \) may be characterized by specifying its size (amplitude of \( B_\zeta \)), shape (whether \( B_\zeta \) peaks on squeezed, equilateral or flattened triangles) and running (the dependence of \( B_\zeta \) on the size of the triangle). The various nongaussian scenarios discussed above may be classified according to the size, shape and running of the bispectrum, see [72] for a more detailed review.

The nongaussian signature from IR cascading is very different from other models, such as the local, equilateral or enfolded shapes, which have been studied in the literature. IR cascading only influences modes leaving the horizon near the moment \( \phi = \phi_0 \), when particle production occurs, hence we expect the bispectrum to be very far from scale invariant (this is also true for the model considered in [51, 52]). The dominant contribution to \( B_\zeta(k_i) \) should peak strongly for triangles with a characteristic size \( \sim k_{\text{IR}} \), corresponding to the location of the bump in the power spectrum (16). We will estimate the shape of the bispectrum from particle production and IR cascading in more detail in section [14] and re-visit this issue also in an upcoming publication [73].

The unusual shape and strong scaling properties of the bispectrum from particle production makes it difficult to compare the magnitude of nongaussianity in this model to more familiar bispectra, such as the local shape, which are very close to scale invariant. We find it useful to quantify the magnitude of the nongaussianity in the model (11) by computing the moments of the Probability Distribution Function (PDF), \( P(\zeta) \), which is the probability that the curvature perturbation has a fluctuations of size \( \zeta \). These moments carry information about the correlation functions of \( \zeta \) integrated over all wavenumbers \( k_i \) and therefore provide a useful tool to compare models with very different shape/running properties [77] (See also
Let us define the central moments of the PDF as
\[ \langle \zeta^n \rangle = \int \zeta^n P(\zeta) d\zeta \]  
(18)

The \( n \)-th cumulant \( \kappa_n \) is the connected \( n \)-point function. For \( \langle \zeta \rangle = 0 \) the first few non-vanishing cumulants are:
\[ \kappa_2 = \langle \zeta^2 \rangle = \sigma_{\zeta}^2 \]  
(19)
\[ \kappa_3 = \langle \zeta^3 \rangle \]  
(20)
\[ \kappa_4 = \langle \zeta^4 \rangle - 3\langle \zeta^2 \rangle^2 \]  
(21)
\[ \kappa_5 = \langle \zeta^5 \rangle - 10\langle \zeta^3 \rangle\langle \zeta^2 \rangle \]  
(22)

It is useful to introduce the dimensionless cumulants, defined as
\[ \hat{\kappa}_n = \frac{\kappa_n}{\langle \zeta^2 \rangle^{n/2}} \]  
(23)

For a gaussian PDF we have \( \hat{\kappa}_n = 0 \) for \( n \geq 3 \), hence these quantity departures from gaussian statistics. When the nongaussianities are small, \( |\hat{\kappa}_{n>3}| \ll 1 \), then the corrections to \( P(\zeta) \) are well described by the Edgeworth expansion:
\[ P(\zeta) = \frac{1}{\sqrt{2\pi} \sigma_{\zeta}} e^{-(\zeta^2)/(2\sigma_{\zeta}^2)} \left[ 1 + \frac{\hat{\kappa}_3}{3!} H_3 \left( \frac{\zeta}{\sigma_{\zeta}} \right) + \cdots \right] \]  
(24)

where \( H_3(x) = x^3 - 3x \) is a Hermite polynomial and the \( \cdots \) denotes corrections of order \( \hat{\kappa}_4, \hat{\kappa}_5 \) and smaller. See [1, 27, 28] for more details and [51] for an alternative derivation.

### III. Nongaussianity of the Probability Distribution Function

In order to quantify the magnitude of the nongaussianity generated by particle production, let us now consider the PDF in the model [1]. We proceed numerically, re-visiting the lattice field theory simulations performed in [1] using the HLattice code [24]. For illustration, we assume the standard chaotic inflation model \( V(\phi) = m^2\phi^2/2 \) with \( m \approx 10^{-6}\sqrt{8\pi M_p} \) and \( \phi_0 = 3.2\sqrt{8\pi M_p} \). We consider three different choices of coupling, \( g^2 = 1, 0.1, 0.01 \). Our simulations are performed in a 512^3 box whose co-moving size is initially \( \sim 3 \) times the horizon size \( H^{-1} \). We run our simulations for roughly 3 e-foldings from the moment when \( \phi = \phi_0 \), which is more than enough to see the feature from IR cascading freeze out as an observable, super-horizon density fluctuation. Our choice of \( \phi_0 \) ensures that the feature will be frozen-in at scales slightly smaller than the current horizon. Note that our quantitative results do not depend sensitively on the choice of \( \phi_0 \), nor on the details of the background inflationary potential \( V(\phi) \); see [1] for further discussion.

We extract the PDF of \( \delta\phi \) from our HLattice simulations by measuring the fraction of the simulation box which contains the fluctuation field \( \delta\phi \) at a particular value. Notice that this approach is completely nonperturbative: it does not rely on the validity of the Edgeworth expansion, nor does it assume anything about the size or ordering of the cumulants. This procedure implicitly puts a IR cut-off at the box size \( L \) and a UV cut-off at the lattice spacing, \( \Lambda^{-1} \). Since the nongaussian effects in our model are strongly localized in Fourier space, our quantitative results are largely insensitive to \( L \) and \( \Lambda \).

In Fig. 2 we plot our numerical result for the PDF of the inflaton fluctuations generated by rescattering and IR cascading. In order to make the physics of inflationary particle production clear, we have subtracted off the contribution coming from the usual vacuum fluctuations of the inflaton. That is, the PDF in Fig. 2 is associated only with the contribution \( \delta\phi_{\text{resc}} \) in equation (19).

[78] for a related discussion and alternative methodology.)

For a gaussian PDF we have \( \hat{\kappa}_n = 0 \) for \( n \geq 3 \), hence these quantity departures from gaussian statistics. When the nongaussianities are small, \( |\hat{\kappa}_{n>3}| \ll 1 \), then the corrections to \( P(\zeta) \) are well described by the Edgeworth expansion:

\[ P(\zeta) = \frac{1}{\sqrt{2\pi} \sigma_{\zeta}} e^{-(\zeta^2)/(2\sigma_{\zeta}^2)} \left[ 1 + \frac{\hat{\kappa}_3}{3!} H_3 \left( \frac{\zeta}{\sigma_{\zeta}} \right) + \cdots \right] \]  
(24)

where \( H_3(x) = x^3 - 3x \) is a Hermite polynomial and the \( \cdots \) denotes corrections of order \( \hat{\kappa}_4, \hat{\kappa}_5 \) and smaller. See [1, 27, 28] for more details and [51] for an alternative derivation.

### III. Nongaussianity of the Probability Distribution Function

In order to quantify the magnitude of the nongaussianity generated by particle production, let us now consider the PDF in the model [1]. We proceed numerically, re-visiting the lattice field theory simulations performed in [1] using the HLattice code [24]. For illustration, we assume the standard chaotic inflation model \( V(\phi) = m^2\phi^2/2 \) with \( m \approx 10^{-6}\sqrt{8\pi M_p} \) and \( \phi_0 = 3.2\sqrt{8\pi M_p} \). We consider three different choices of coupling, \( g^2 = 1, 0.1, 0.01 \). Our simulations are performed in a 512^3 box whose co-moving size is initially \( \sim 3 \) times the horizon size \( H^{-1} \). We run our simulations for roughly 3 e-foldings from the moment when \( \phi = \phi_0 \), which is more than enough to see the feature from IR cascading freeze out as an observable, super-horizon density fluctuation. Our choice of \( \phi_0 \) ensures that the feature will be frozen-in at scales slightly smaller than the current horizon. Note that our quantitative results do not depend sensitively on the choice of \( \phi_0 \), nor on the details of the background inflationary potential \( V(\phi) \); see [1] for further discussion.

We extract the PDF of \( \delta\phi \) from our HLattice simulations by measuring the fraction of the simulation box which contains the fluctuation field \( \delta\phi \) at a particular value. Notice that this approach is completely nonperturbative: it does not rely on the validity of the Edgeworth expansion, nor does it assume anything about the size or ordering of the cumulants. This procedure implicitly puts a IR cut-off at the box size \( L \) and a UV cut-off at the lattice spacing, \( \Lambda^{-1} \). Since the nongaussian effects in our model are strongly localized in Fourier space, our quantitative results are largely insensitive to \( L \) and \( \Lambda \).

In Fig. 2 we plot our numerical result for the PDF of the inflaton fluctuations generated by rescattering and IR cascading. In order to make the physics of inflationary particle production clear, we have subtracted off the contribution coming from the usual vacuum fluctuations of the inflaton. That is, the PDF in Fig. 2 is associated only with the contribution \( \delta\phi_{\text{resc}} \) in equation (19).
We can understand physically the behaviour of PDF plotted in Fig. 2. Shortly after the initial burst of particle production the inflaton perturbations $\delta \phi$ are extremely nongaussian, due to the sudden appearance of the source term $J \propto \chi^2$ in the equation of motion. Very quickly, in less than an $e$-folding, nonlinear interactions begin to drive the system towards gaussianity. A very similar behaviour has been observed in lattice simulations of out-of-equilibrium interacting scalar fields during preheating. In the case of rescattering during preheating, the system will eventually become gaussian when the fields thermalize. However, in our case the universe is still inflating. As a result, nongaussian inflaton fluctuations generated by rescattering are stretched out by the quasi-de Sitter expansion and must freeze once their wavelength crosses the Hubble scale. Hence, at late times the PDF does not become completely gaussian, but rather freezes-in with some non-trivial skewness. Within a few $e$-foldings from the moment of particle production the time evolution of the PDF has become completely negligible.

In order to characterize the nongaussianity of the observable primordial fluctuations, we would like to construct the PDF for the curvature perturbation $\zeta$, including both the contributions from the vacuum fluctuations of the inflaton and also from rescattering. To this end, we construct $\zeta$ using the naive relation $\zeta = -\frac{D}{\phi} \delta \phi$ (see section [V] for justification) and take into account both contributions to $\delta \phi$ in equation (15). In Fig. 3 we plot the full PDF obtained in this manner, evaluated at very late times, well after all relevant modes have crossed the horizon and become frozen.

Given our numerical results for the PDF of the total observable curvature fluctuation, $\zeta$, at late times (well after all relevant modes have crossed the horizon and frozen). The solid black curve is the exact result from our HLattice simulations and the dotted red curve is a gaussian fit. We have also plotted the leading correction to the gaussian result in the Edgeworth expansion, given explicitly by equation (24). For illustration, we have chosen $g^2 = 0.1$ and a standard chaotic inflation potential $V(\phi) = m^2 \phi^2/2$.

![FIG. 2: The PDF of the inflaton fluctuations generated by rescattering and IR cascading, at a series of different values of the scale factor, $a$. The dotted black curve shows a Gaussian fit at late times and we have normalized the scale factor so that $a = 1$ at the moment when particle production occurs. For illustration, we have chosen $g^2 = 0.1$ and a standard chaotic inflation potential $V(\phi) = m^2 \phi^2/2$.](image)

TABLE I: Moments of the Probability Distribution Function

| $g^2$ | skewness $\hat{\kappa}_3$ | kurtosis $\hat{\kappa}_4$ | 5-th moment “equivalent” $f_{NL}$ local |
|-------|-----------------|-----------------|-----------------|
| 1     | -0.51           | 0.2             | 1.2             | -4500 |
| 0.1   | -0.49           | -0.1            | 1.5             | -4300 |
| 0.01  | -0.006          | < $\mathcal{O}(10^{-3})$ | < $\mathcal{O}(10^{-3})$ | -53 |

data for any choice of $\phi_0$ [2] we still obtain a skewness $\hat{\kappa}_3 = -0.006$, which is the same value that would be produced by a local model with $f_{NL} \sim -53$. This “equivalent” local nongaussianity is comparable to current observational bounds, and is well within the expected accuracy of future missions. This suggests that nongaussian features from particle production during inflation might be observable for reasonable values of $g^2$.

The “equivalent” $f_{NL}$ local values presented in Table I must be interpreted with care. We have included this information only to give a heuristic sense of the magnitude of nongaussianity in our model. It must be stressed that the PDF plotted in Fig. 8 is quite different from the analogous result for local-type nongaussianity. For example, the value of the kurtosis (and higher moments) are different, as is the ordering of the cumulants. Moreover, we should emphasize that observational bounds on $f_{NL}$ local cannot be directly applied to our model since the bispectrum feature in our case is uncorrelated with the vacuum fluctuations and is far from scale invariant. A detailed study of the detectability of nongaussianity from particle production will be the subject of a future publication.

Depending on the value of $\phi_0$, the model [1] may lead to a variety of observable signatures. As discussed previously, $\phi_0$ controls the location of the feature in the primordial power spectrum [16]. Nongaussian effects are also localized near the same characteristic scale, $k_{IR}$. If $k_{IR}$ corresponds to scales relevant for CMB experiments, then we predict a bump-like feature in the primordial power spectrum, $P_{\delta\delta}$, and an associated feature in the bispectrum $B_{\langle \delta \delta \rangle (k)}$ with an unusual shape (that will be discussed in section IV). A key question is whether the nongaussian feature can be observable in a regime where the power spectrum feature is small enough to be compatible with current observations. Preliminary results are encouraging: for $g^2 = 0.01$ the power spectrum is consistent with all observational data [2] while the skewness of the PDF is rather large. A detailed investigation will require a simple, separable template for the bispectrum and will be discussed in a future publication.

On the other hand, we could imagine a scenario where the feature from IR cascading shows up on smaller scales, relevant for Large Scale Structure (LSS) experiments [17, 83, 82]. In this case our scenario could be probed using higher order correlations of LSS probes (such as the galaxy bispectrum) or the abundance of collapsed objects (or voids). The latter possibility is interesting since the cluster/void abundance is determined tails of the PDF and may be insensitive to the detailed shape of the bispectrum. Quantitative predictions for observable cluster/void abundances require the PDF of the evolved density field, smoothed on some relevant scale [73], rather than the PDF of the primordial curvature perturbation (which is plotted in Fig. 8). However, we can nevertheless describe the qualitative signatures which should be expected. Our model robustly predicts a negative skewness for both the curvature perturbation, $\zeta$, and the density field, $\delta R / \rho$. Hence, we should expect a decrease in the abundance of the largest collapsed objects and an increase in the abundance of the largest voids [87, 88]. Owing to the localized nature of the bispectrum feature, we expect that this effect should show up only when the density field is smoothed on a scale close to $k_{IR}$.

It is worth mentioning that recent weak lensing measurement of the dark matter mass of the high-redshift galaxy cluster XMMUJ2235.3-2557 [50] have been construed as a possible hint of nongaussian initial conditions [40]. Unfortunately, our model does not produce the correct sign of skewness to explain such observations.

IV. ANALYTICAL FORMALISM

In [1] we studied particle production, rescattering and IR cascading using nonlinear lattice field theory simulations. In addition to this numerical approach, a cursory analytical formalism was also presented. Here we re-visit the analytical analytical theory of particle production, rescattering and IR cascading in an expanding universe, in order to better understand the results of [1] from a physical perspective.

A. The Prototype Model

We consider now the theory

$$S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R - \frac{1}{2} (\partial \phi)^2 - V(\phi) - \frac{1}{2} (\partial \chi)^2 - \frac{\mu^2}{2} \chi^2 - \frac{g^2}{2} (\phi - \phi_0)^2 \chi^2 \right]$$

(25)

which differs from our original model [2] by the inclusion of a mass term $\Delta \mathcal{L} = -\mu^2 \chi^2 / 2$ for the iso-inflaton. Such a term is not forbidden by any symmetry and hence one typically expects it to be generated by radiative corrections, even if the iso-inflaton is classically massless at $\phi = \phi_0$. The new parameter $\mu$ has the effect of reducing the efficiency of the particle production effects discussed in subsection IIA; the time-varying mass of the iso-inflaton

$$m_\chi^2 = \mu^2 + g^2 (\phi - \phi_0)^2$$
does not vanish at $\phi = \phi_0$, but rather reaches a minimum value $\mu^2$, making the adiabaticity condition more difficult to violate. A concern is the possibility that radiative corrections induce a large $\mu$ and suppress the observable effects associated with inflationary particle production. Indeed, it is well known that fine tuning may be required to keep the mass of any scalar field significantly below the cut-off scale associated with the validity of the effective field theory description (25). Below, we will show that the suppression of $\chi$-particle production is not significant provided the following condition is satisfied

$$\mu^2 \ll k_*^2$$

(26)

where $k_* \equiv \sqrt{g/v}$. Depending on how (26) is embedded within a more complete framework, the constraint (26) may (or may not) require fine-tuning to satisfy. Below, we will show that the condition (26) is quite naturally satisfied for a large number of microscopically realistic scenarios.

Our prototype model (25) has been chosen to elucidate the key physics and observational signatures of inflationary particle production in a simple framework wherein computations are tractable. We expect, however, that many of our qualitative results will carry over to more complicated scenarios. In particular, one might wish to supplement the action (25) by its supersymmetric (SUSY) completion; see the interesting work [27] for an explicit example. Such an embedding has the advantage that the flatness of the inflaton potential $V(\phi)$ may be protected from large radiative corrections coming from loops of the $\chi$ field. Moreover, a SUSY embedding of the model (25) also allows for some control over the quantum corrections to the mass scale $\mu$.

For models obtained from string theory or supergravity (SUGRA), it is natural to have $\mu$ of order the Hubble scale$^3$ during inflation [38–40]; hence we expect $\mu^2 \sim H^2$ for such models. In that case, the constraint (26) is automatically satisfied, because $k_*^2 \ll H^2$ whenever particle production is fast as compared to the expansion time (that is, for reasonable values of the coupling $g^2 > 10^{-7}$, which we assume throughout this work). Hence, there exists a very large class of realistic microscopic models in which radiative effects will not spoil the observational consequences of inflationary particle production and IR cascading.

Although the condition for the efficiency of particle production - that is equation (26) - can be easily satisfied for models coming from string theory or SUSY, we prefer to remain agnostic regarding how the prototype action (25) is embedded within a more complete framework. Throughout our analysis we will keep the inflaton potential $V(\phi)$ and the iso-inflaton mass parameter $\mu$ more-or-less arbitrary (we assume that the slow roll conditions are satisfied, and also that $\mu^2 > 0$). This phenomenological approach is not different from the philosophy that is employed in the majority of work on inflationary cosmology, since the slow roll conditions [41] may be sensitive to UV physics whose detailed form is often not specified. The question of how the model (25), with a given choice of $V(\phi)$ and $\mu$, arises from some complete model of particle physics is interesting. However, this question it is not the main focus of the current investigation. We refer the reader to [2] for several example microscopic embeddings within string theory and also SUSY (see also [3]).

Let us now proceed to develop an analytical formalism to study inflationary particle production in the model (25). The equations of motion that we wish to solve are

$$-\Box \phi + V'(\phi) + g^2(\phi - \phi_0)\chi^2 = 0$$

$$-\Box \chi + \left[\mu^2 + g^2(\phi - \phi_0)^2\right] \chi = 0$$

(27)

(28)

where $\Box = g_{\mu\nu}\nabla^\mu \nabla^\nu$ is the covariant d’Alembertian. It will be useful to work with conformal time $\tau$, related to cosmic time $t$ via $d\tau = dt$. In terms of conformal time the metric takes the form

$$ds^2 = -dt^2 + a^2(t)dx \cdot dx$$

$$= a^2(\tau) \left[-d\tau^2 + dx \cdot dx\right]$$

(29)

We denote derivatives with respect to cosmic time as $\dot{f} \equiv \partial_\tau f$ and with respect to conformal time as $f' \equiv \partial_\tau f$. The Hubble parameter $H = \dot{a}/a$ has conformal time analogue $\mathcal{H} = a'/a$. For an inflationary (quasi-de Sitter) phase $(H \cong \text{const})$ one has

$$a = -\frac{1}{H\tau - 1 - \epsilon}, \quad \mathcal{H} = -\frac{1}{\tau - 1 - \epsilon}$$

(30)

to leading order in the slow roll parameter $\epsilon \ll 1$.

As discussed in section I the motion of the homogeneous inflaton $\phi(t)$ leads to the production of a gas of $\chi$ particles at the moment $t = 0$ when $\phi = \phi_0$. The first step in our analytical computation is to describe this burst of particle production in an expanding universe. Following the initial burst, both backreaction and rescattering effects take place. Our formalism will focus on the latter effect, which has been shown to be much more important [1].

B. Particle Production in an Expanding Universe

The first step in our scenario is the quantum mechanical production of $\chi$-particles due to the motion of $\phi$. To understand this effect we must solve the equation for the
\( \chi \) fluctuations in the rolling inflaton background. Approximating \( \phi \approx \phi_0 + vt \) equation (28) gives

\[
\ddot{\chi} + 3H \dot{\chi} - \frac{\nabla^2}{a^2} \chi + [\mu^2 + k_\chi^2] \chi = 0 \tag{31}
\]

where \( k_\chi \equiv \sqrt{g/|\mu|} \). We remind the reader that \( k_\chi \gg H \) for reasonable values of the coupling, see equation (32).

The flat space analogue of equation (31) is very well understood from studies of broad band parametric resonance during preheating [42] and also moduli trapping at enhanced symmetry points [33]. One does not expect this treatment to differ significantly in our case since both the time scale for particle production \( \Delta t \) and the characteristic wavelength of the produced fluctuations \( \lambda \) are small compared to the Hubble scale. Hence, we expect that the occupation number of produced \( \chi \) particles will not differ significantly from the flat-space result, at least on scales \( k \lesssim H \). Furthermore, notice that the \( \chi \) field is extremely massive for most of inflation. Indeed, even in the case \( \mu^2 = 0 \) we have

\[
\frac{m_\chi^2}{H^2} \sim \frac{k_\chi^4 t^2}{H^2} \tag{32}
\]

Since \( k_\chi \gg H \) it follows that \( m_\chi^2 \gg H^2 \), except in a tiny interval \( H |\Delta t| \sim (H/k_\chi)^2 \) which amounts to roughly \( 10^{-3} \) e-foldings for \( g^2 \sim 0.1 \). Therefore, we do not expect any significant fluctuations of \( \chi \) to be produced on super-horizon scales \( k \lesssim H \). (Allowing for \( \mu^2 \neq 0 \) only strengthens this conclusion.)

Let us now consider the solutions of equation (31). We work with conformal time \( \tau \) and write the Fourier transform of the quantum field \( \chi \) as

\[
\chi(\tau, \mathbf{x}) = \int \frac{d^3k}{(2\pi)^{3/2}} \frac{\xi_k(\tau)}{a(\tau)} e^{ik \cdot \mathbf{x}} \tag{33}
\]

Note the explicit factor of \( a^{-1} \) in (33) which is introduced to give \( \xi_k \) a canonical kinetic term. The \( q \)-number valued Fourier transform \( \xi_k(\tau) \) can be written as

\[
\xi_k(\tau) = a_k \chi_k(\tau) + a_k^\dagger \chi_k^*(\tau) \tag{34}
\]

where the annihilation/creation operators satisfy the usual commutation relation

\[
[a_k, a_{k'}^\dagger] = \delta^{(3)}(k - k') \tag{35}
\]

and the \( c \)-number valued mode functions \( \chi_k \) obey the following oscillator-like equation

\[
\chi_k''(\tau) + \omega_k^2(\tau) \chi_k(\tau) = 0 \tag{36}
\]

The time-dependent frequency is

\[
\omega_k^2(\tau) = k^2 + a^2 m_\chi^2(\tau) - \frac{a''}{a} \approx k^2 + \frac{1}{\tau^2} \left[ \frac{k_\chi^4}{H^2} t^2(\tau) + \left( \frac{\mu}{H} \right)^2 - 2 \right] \tag{37}
\]

where

\[
m_\chi^2(\tau) = \mu^2 + g^2 (\phi - \phi_0)^2 \cong \mu^2 + k_\chi^4 t^2(\tau) \tag{38}
\]

is the time-dependent effective mass of the \( \chi \) particles and

\[
t(\tau) = \frac{1}{H} \ln \left( \frac{-1}{H \tau} \right) \tag{39}
\]

is the usual cosmic time variable. We have arbitrarily set the origin of conformal time so that \( \tau = -1/H \) corresponds to the moment when \( \phi = \phi_0 \).

It is useful to define the occupation number \( n_k \) of the \( \chi \) particles with momentum \( k \), defined as the energy of the mode \( k^2 |\chi_k|^2 + \frac{1}{2} \omega_k^2 |\chi_k|^2 \) divided by the energy \( \omega_k \) of each particle. Explicitly, we define

\[
n_k = \frac{\omega_k}{2} \left[ \frac{|\chi_k|^2}{\omega_k^2} + |\chi_k|^2 \right] - \frac{1}{2} \tag{40}
\]

where the term \(-\frac{1}{2}\) comes from extracting the zero-point energy of the linear harmonic oscillator (see [42] for a review). Our definition (40) coincides with the usual notion of particle number in the asymptotic adiabatic regimes \( |t| \approx k_\chi^{-1} \). During the very brief non-adiabatic period \( |t| \ll k_\chi^{-1} \) our result coincides with the usual notion of quasi-particle number, obtained by instantaneous diagonalization of the Hamiltonian.

Let us now try to understand analytically the behaviour of the solutions of (36). At early times \( t \ll k_\chi^{-1} \), the frequency \( \omega_k \) varies adiabatically

\[
|\frac{\omega_k'}{\omega_k}| \ll 1 \tag{41}
\]

In this in-going adiabatic regime the modes \( \chi_k \) are not excited and the solution of (36) are well described by the adiabatic solution \( \chi_k(\tau) = f_k(\tau) \) where

\[
f_k(\tau) = \frac{1}{\sqrt{2\omega_k(\tau)}} \exp \left[ -i \int d\tau' \omega_k(\tau) \right] \tag{42}
\]

We have normalized [42] to be pure positive frequency so that the state of the iso-inflaton field at early times corresponds to the adiabatic vacuum with no \( \chi \) particles. (Inserting (42) into (40) one finds \( n_k = 0 \) for the adiabatic solution, as expected.)

The adiabatic solution (42) ceases to be a good approximation very close to the moment when \( \phi = \phi_0 \), that is at times \( |t| \approx k_\chi^{-1} \). In this regime the adiabaticity condition (41) is violated for modes with wave-number \( H \lesssim k \lesssim \sqrt{k_\chi^2 - \mu^2} \) and \( \chi \) particles within this momentum band are produced. During the non-adiabatic regime we can still represent the solutions of (36) in terms of the functions \( f_k(\tau) \) as

\[
\chi_k(\tau) = a_k(\tau)f_k(\tau) + \beta_k(\tau)f_k^*(\tau) \tag{43}
\]
This expression affords a solution of (36) provided the time-dependent Bogoliubov coefficients obey the following set of coupled equations

\[
\alpha'_k(\tau) = \frac{\omega_k(\tau)}{2\omega_k(\tau)} \exp\left[+2i \int_\tau^T d\tau' \omega_k(\tau')\right] \beta_k(\tau) \tag{44}
\]

\[
\beta'_k(\tau) = \frac{\omega_k(\tau)}{2\omega_k(\tau)} \exp\left[-2i \int_\tau^T d\tau' \omega_k(\tau')\right] \alpha_k(\tau) \tag{45}
\]

The Bogoliubov coefficients are normalized as \(|\alpha_k|^2 - |\beta_k|^2 = 1\) and the assumption that no \(\chi\) particles are present in the asymptotic past\(^4\) fixes the initial conditions \(\alpha_k = 1\), \(\beta_k = 0\) for \(t \to -\infty\). This is known as the adiabatic initial condition.

From the structure of equations (44)-(45) it is clear that violations of the condition (41) near \(t = 0\) leads to a rapid growth in the \(|\beta_k|\) coefficient. The time variation of \(\beta_k\) can be interpreted as a corresponding growth in the occupation number. Inserting (45) into (44) we find

\[
n_k = |\beta_k|^2 \tag{46}
\]

At late times (\(t \gtrsim k_{\ast}^{-1}\)) adiabaticity is restored and the growth of \(n_k = |\beta_k|^2\) must saturate. By inspection of equations (44)-(45) we can see that the Bogoliubov coefficients must tend to constant values in the out-going adiabatic regime. Therefore, within less than an \(e\)-folding from the moment of particle production the solution \(\chi_k\) of equation (36) can be represented as a simple superposition of positive frequency \(f_k\) modes and negative frequency \(f_k^\star\) modes. Our goal now is to derive an analytical expression for the modes \(\chi_k\) which is valid in this out-going adiabatic region.

First, we seek an expression for the Bogoliubov coefficients \(\alpha_k, \beta_k\) in the out-going adiabatic regime \(t \gtrsim k_{\ast}^{-1}\). From (44)-(45) it is clear that the value of the Bogoliubov coefficients at late times can depend only on dynamics during the interval \(|t| \lesssim k_{\ast}^{-1}\) where the adiabaticity condition (41) is violated. This interval is tiny compared to the expansion time and we are justified in treating \(a(\tau)\) as roughly constant during this phase. Hence, it follows that the flat space computation of the Bogoliubov coefficients (33)-(34) must apply, at least for scales \(k \gtrsim H\). To a very good approximation we therefore have the well-known result

\[
\alpha_k \cong \sqrt{1 + e^{-\pi \mu^2/k_{\ast}^2} e^{-\pi k^2/k_{\ast}^2}} \tag{47}
\]

\[
\beta_k \cong -ie^{-\pi \mu^2/(2k_{\ast}^2)} e^{-\pi k^2/(2k_{\ast}^2)} \tag{48}
\]

in the out-going adiabatic regime. Equation (48) gives the usual expression\(^5\) for the co-moving occupation number of particles produced by a single burst of broad-band parametric resonance:

\[
n_k = |\beta_k|^2 = e^{-\pi \mu^2/k_{\ast}^2} e^{-\pi k^2/k_{\ast}^2} \tag{49}
\]

Comparing equations (49) and (10) we see that the mass parameter \(\mu\) for the iso-inflaton has the effect of suppressing the number density of produced \(\chi\) particles by an amount \(e^{-\pi \mu^2/k_{\ast}^2} \lesssim 1\). This suppression reflects the reduced phase space of produced particles: the adiabaticity condition is violated only for modes with \(k < \sqrt{k_{\ast}^2 - \mu^2}\). Notice that the suppression of \(\chi\) particle production is negligible when \(\mu^2 \ll k_{\ast}^2\), precisely the condition (26) that was alluded to earlier. For the remainder of this work we will assume that \(\mu \lesssim k_{\ast}\), since in the opposite regime the observational signatures of particle production effects are exponentially suppressed.

Next, we seek an expression for the adiabatic solution \(f_k(\tau)\) in the out-going regime \(t \gtrsim k_{\ast}^{-1}\). We assume \(\mu \lesssim k_{\ast}\) and also focus on the interesting region of phase space, \(H \lesssim k \gtrsim \sqrt{k_{\ast}^2 - \mu^2}\). In this case, the adiabatic solution (42) is very well approximated by

\[
f_k(\tau) \cong \frac{1}{a^{1/2} k_{\ast} \sqrt{2f(\tau)}} e^{-\frac{1}{2} k^2 t^2(\tau)} \tag{50}
\]

where \(t(\tau)\) is defined by (49). It is interesting to note that equation (50) is identical to the analogous flat-space result (10), except for the factor of \(a^{-1/2}\). Taking into account also the explicit factor of \(a^{-1}\) in our definition of the Fourier transform (33) we recover the expected large-scale behaviour for a massive field in de Sitter space, that is \(\chi \sim a^{-3/2}\). This dependence on the scale factor is easy to understand physically, it simply reflects the volume dilution of non-relativistic particles: \(\rho_{\chi} \sim m_{\chi}^2 \chi^2 \sim a^{-3}\). Notice that the parameter \(\mu\) does not appear in (50). This is so because, for the time-varying mass of the \(\chi\) field, equation (38) is dominated by the interaction term when \(k_{\ast}|t| \gtrsim 1\) and \(\mu \lesssim k_{\ast}\).

Finally, we arrive at an expression for the out-going adiabatic \(\chi\) modes which is accurate for interesting scales \(H \lesssim k \lesssim \sqrt{k_{\ast}^2 - \mu^2}\). Putting together the results (50) and (48) along with the well-known expressions (47)-(48) we arrive at

\[
\chi_k(\tau) \cong \sqrt{1 + e^{-\pi \mu^2/k_{\ast}^2} e^{-\pi k^2/k_{\ast}^2}} \frac{1}{a^{1/2} k_{\ast} \sqrt{2f(\tau)}} e^{-\frac{1}{2} k^2 t^2(\tau)}
\]

\[
-\frac{1}{a^{1/2} k_{\ast} \sqrt{2f(\tau)}} e^{\frac{1}{2} k^2 t^2(\tau)} \tag{51}
\]

valid for \(t \gtrsim k_{\ast}^{-1}\). Equation (51) is the main result of this subsection. We will now justify that this expression is quite sufficient for our purposes.

\(^4\) This assumption is justified since any initial excitation of \(\chi\) would have been damped out exponentially fast by the expansion of the universe.

\(^5\) Our result for the Bogoliubov coefficients is consistent with (33).
For modes deep in the UV, \( k \gtrsim k_* \), our expression (51), is not accurate.\(^6\) However, such high momentum particles are not produced, the condition (11) is always satisfied for \( k \gg k_* \). Note that the absence of particle production deep in the UV is built into our expression (51): as \( k \to \infty \) this function tends to the vacuum solution \( \chi_k \to \mathcal{f}_k \).

Our expression (11) is also not valid deep in the IR, for modes \( k < H \). To justify this neglect requires somewhat more care. Notice that, even very far from the point \( \phi = \phi_0 \) long wavelength modes \( k \ll H \) should not be thought of as particle-like. The large-scale mode functions are not oscillatory but rather damp exponentially fast as \( \chi \sim a^{-3/2} \). Hence, even if we started with some super-horizon fluctuations of \( \chi \) at the beginning of inflation, these would be suppressed by an exponentially small factor before the time when particle production occurs. Any super-horizon fluctuation generated near \( t = 0 \) would need to be exponentially huge to overcome this damping. However, resonant particle production during inflation does not lead to exponential growth of mode functions.\(^7\)

To verify explicitly that there is no significant effect for super-horizon fluctuations let us consider solving equation (31) neglecting gradient terms. The equation we wish to solve, then, is

\[
\partial_t^2(a^{3/2}\chi) + \left[k_*^2 t^2 - \frac{9}{4} H^2\right](a^{3/2}\chi) = 0
\]

(52)

(For simplicity we take \( \mu = 0 \) and \( \epsilon = 0 \) for this paragraph, however, this has no effect on our results.) The solution of this equation may be written in terms of parabolic cylinder functions \( D_\nu(z) \) as

\[
\chi(t, x) \sim \frac{1}{a^{3/2}} \left( C_1 D_{-\frac{3}{4} + \frac{3}{8} i} \left[ (1+i)k_* t \right] + C_2 D_{-\frac{3}{4} - \frac{3}{8} i} \left[ (-1+i)k_* t \right] \right)
\]

(53)

For our purposes the precise values of the coefficients \( C_1, C_2 \) are not important. Rather, it suffices to note that for \( k_* |t| \gtrsim 1 \) the function (53) behaves as

\[
\chi(t, x) \sim |t|^{-1/2} e^{-3Ht/2} \times \text{[oscillatory]}
\]

(54)

This explicit large-scale asymptotics confirms our previous claims that the super-horizon fluctuations of \( \chi \) damp to zero exponentially fast, as \( a^{-3/2} \sim e^{-3Ht/2} \). As discussed previously, this damping is easy to understand in terms of the volume dilution of non-relativistic particles. (If we had included the parameter \( \mu^2 \) in equation (52), then our conclusions would only be strengthened, since this parameter has the effect of making the inflaton even more massive.) We can also understand the power-law damping that appears in (53) from a physical perspective. The properly normalized modes behave as \( a^{3/2} \chi \sim \omega_k^{-1/2} \) while on large scales we have \( \omega_k \sim |m_\chi| \sim |t| \). Hence, the late-time damping factor \( \omega_k^{-1/2} \) which appears in (53) reflects the fact that the \( \chi \) particles become ever more massive as \( \phi \) rolls away from the point \( \phi_0 \).

Finally, it is straightforward to see that the function (53) does not display any exponential growth near \( t = 0 \). Hence, we conclude that there is no significant generation of super-horizon \( \chi \) fluctuations due to particle production.\(^8\)

In this subsection we have seen that the quantum production of \( \chi \) particles in an expanding universe proceeds very much as it does in flat space. This is reasonable since particle production occurs on a time scale short compared to the expansion time and involves modes which are inside the horizon at the time of production.

C. Inflaton Fluctuations

In section IVB we studied the quantum production of \( \chi \) particles which occurs when \( \phi \) rolls past the massless point \( \phi = \phi_0 \). Subsequently, there are two distinct physical processes which take place: backreaction and rescattering. As we discussed, the former effect has a negligible impact of the observable spectrum of cosmological perturbations and may be neglected.

In this subsection we study the rescattering of produced \( \chi \) particles from the inflaton condensate. The dominant process to consider is the diagram illustrated in Fig. 11 corresponding to bremsstrahlung emission of \( \delta \phi \) fluctuations (particles) in the background of the external field. (There is also a sub-dominant process of the type \( \chi \chi \rightarrow \delta \phi \delta \phi \) which is phase space suppressed.) Taking into account only the rescattering diagram illustrated in Fig. 11 is equivalent to solving the following equation for

\footnotesize

\(^6\) The expression (53) for the adiabatic modes \( \mathcal{f}_k \) is not valid at high momenta where \( \omega_k \cong k \).

\(^7\) In this regard our scenario is very different from preheating at the end of inflation. In the latter case the inflaton passes many times through the massless point \( m_\chi = 0 \) and there are, correspondingly, many bursts of particle production. After many oscillations of the inflaton field, the \( \chi \) particle occupation numbers build up to become exponentially large and, averaged over many oscillations of the background, the \( \chi \) mode functions grow exponentially. However, in our case there is only a single burst of particle production at \( t = 0 \). The resulting occupation number (10) is always less than unity and the solutions of (50) never display exponential growth.

\(^8\) This is strictly true only in the linearized theory. It is possible that \( \chi \) particles are generated by nonlinear effects such as rescattering. However, even such second order \( \chi \) fluctuations will be extremely massive compared to the Hubble scale and must therefore suffer exponential damping \( a^{-3/2} \) on large scales.
the q-number inflaton fluctuation

$$\frac{\partial^2}{\partial \tau^2} + 3H\frac{\partial}{\partial \tau} - \frac{\nabla^2}{a^2} + m^2 \delta \phi = -g^2 [\phi(t) - \phi_0] \chi^2$$  \hspace{1cm} (55)

where we have introduced the notation $m^2 \equiv V_{,\phi \phi}$ for the inflaton effective mass. (Note that we are not assuming a background potential of the form $m^2\phi^2/2$, only that $V_{,\phi \phi} \neq 0$ in the vicinity of the point $\phi = \phi_0$.)

Equation (55) may be derived by noting that (29) gives an interaction of the form $g^2(\phi - \phi_0)\delta \phi \chi^2$ between the inflaton and iso-inflaton, in the background of the external field $\phi(t)$. Equivalently, one may construct this equation by a straightforward iterative solution of (27).

We work in conformal time and define the q-number Fourier transform $\xi^\phi_k(\tau)$ of the inflaton fluctuation analogously to (33):

$$\delta \phi(\tau, x) = \int \frac{d^3k}{(2\pi)^{3/2}} \frac{\xi^\phi_k(\tau)}{a(\tau)} e^{ik \cdot x}$$  \hspace{1cm} (56)

(To avoid potential confusion we again draw the attention of the reader to the explicit factor $a^{-1}$ in our convention for the Fourier transform.) The equation of motion (55) now takes the form

$$\left[ \frac{\partial^2}{\partial \tau^2} + k^2 + a^2 m^2 - \frac{a''}{a} \right] \xi^\phi_k(\tau) = -g k^2 a(\tau) t(\tau) \int \frac{d^3k'}{(2\pi)^{3/2}} \xi^\phi_{k'} e^{i(k-k') \cdot x}(\tau)$$  \hspace{1cm} (57)

The solution of (57) consists of two parts: the solution of the homogeneous equation and the particular solution which is due to the source. The former corresponds, physically, to the usual vacuum fluctuations from inflation. On the other hand, the particular solution corresponds physically to the secondary inflaton modes which are generated by rescattering.

D. Homogeneous Solution and Green Function

We consider first the homogeneous solution of (57). Since the homogeneous solution is a gaussian field, we may expand the q-number Fourier transform in terms of annihilation/creation operators $b_k, b^\dagger_k$ and c-number mode functions $\phi_k(\tau)$ as

$$\xi^\phi_k(\tau) = b_k \phi_k(\tau) + b^\dagger_k \phi^*_k(\tau)$$  \hspace{1cm} (58)

Here the inflaton annihilation/creation operators $b_k, b^\dagger_k$ obey

$$[b_k, b^\dagger_{k'}] = \delta^{(3)}(k - k')$$  \hspace{1cm} (59)

and commute with the annihilation/creation operators of the $\chi$-field:

$$[a_k, b^\dagger_{k'}] = [a_k, b_{k'}] = 0$$  \hspace{1cm} (60)

Using (50) and (41) it is straightforward to see that the homogeneous inflaton mode functions obey the following equation

$$\frac{\partial^2}{\partial \tau^2} \phi_k + \left[ k^2 - \frac{1}{\tau^2} \left( \nu^2 - \frac{1}{4} \right) \right] \phi_k = 0$$  \hspace{1cm} (61)

where we have defined

$$\nu \equiv \frac{3}{2} - \eta + \epsilon$$  \hspace{1cm} (62)

The properly normalized mode function solutions are well known and may be written in terms of the Hankel function of the first kind as

$$\phi_k(\tau) = \sqrt{\frac{\tau}{2}} \sqrt{-\tau} H_{\nu}^{(1)}(-k\tau)$$  \hspace{1cm} (63)

This solution corresponds to the usual quantum vacuum fluctuations of the inflaton field during inflation.

In passing, let us compute the power spectrum of the quantum vacuum fluctuations from inflation. Using the solutions (63) we have

$$P^\phi(k) = \frac{k^3}{2\pi^2} \left| \frac{\phi_k}{a} \right|^2 \approx \frac{H^2}{\nu^2} \left( \frac{k}{aH} \right)^{n_s-1}$$  \hspace{1cm} (64)

on large scales $k \ll aH$. The explicit factor of $a^{-2}$ in (63) appears to cancel the $a^{-1}$ in our definition of the Fourier transform (56). The spectral index is

$$n_s - 1 = 3 - 2\nu \approx 2\eta - 2\epsilon$$  \hspace{1cm} (65)

using (62).

Given the solution (63) of the homogeneous equation, it is now trivial to construct the retarded Green function for equation (57). This may be written in terms of the free theory mode functions (63) as

$$G_k(\tau - \tau') = i\Theta(\tau - \tau') \left[ \phi_k(\tau)\phi^*_k(\tau') - \phi^*_k(\tau)\phi_k(\tau') \right]$$

$$= \frac{i\pi}{4} \Theta(\tau - \tau') \sqrt{\nu^2} \left[ H_{\nu}^{(1)}(-k\tau)H_{\nu}^{(1)}(-k\tau')^* - H_{\nu}^{(1)}(-k\tau)^*H_{\nu}^{(1)}(-k\tau') \right]$$  \hspace{1cm} (66)

E. Particular Solution: Rescattering Effects

We now consider the particular solution of (57). This is readily constructed using the Green function (66) as

$$\xi^\phi_k(\tau) =$$

$$-\frac{g k^2}{(2\pi)^{3/2}} \int d\tau' d^3k' G_k(\tau - \tau') a(\tau') t(\tau') \xi^\chi_k e^{i(k-k') \cdot x}(\tau')$$  \hspace{1cm} (67)

Notice that this particular solution is statistically independent of the homogeneous solution (58). In other words, the particular solution can be expanded in terms of the annihilation/creation operators $a_k, a^\dagger_k$ associated
with the $\chi$ field, whereas the homogeneous solution is written in terms of the annihilation/creation operators $b_k, b_k^\dagger$ associated with the inflaton vacuum fluctuations. These two sets of operators commute with one another.

We will ultimately be interested in computing the $n$-point correlation functions of the particular solution (68). For example, carefully carrying out the Wick contractions, the connected contribution to the 2-point function is

$$\langle \xi_{k_1} \xi_{k_2} (\tau) \rangle = \frac{2g^2k_1^4}{(2\pi)^3} \delta^{(3)}(k_1 + k_2)$$

$$\times \int d\tau' d\tau'' a(\tau') a(\tau'') t(\tau') t(\tau'') G_{k_1}(\tau - \tau') G_{k_2}(\tau - \tau'')$$

$$\times \int d^3k' \chi_{k_1 - k'} \chi_{k_2' - k''} \chi_{k_2''}(\tau') \chi_{k_2}(\tau'')$$

(68)

The power spectrum of $\delta \phi$ fluctuations generated by rescattering is then defined in terms of the 2-point function in the usual manner

$$\langle \xi_k^\phi(t) \xi_k^\phi(\tau) \rangle \equiv \delta^{(3)}(k + k') \frac{2\pi^2}{k^3} a(t)^2 P_{\phi}^{\text{resc}}$$

(69)

(The explicit factor of $a^2$ in the definition (69) appears to cancel the factor of $a^{-1}$ in our convention for Fourier transforms (60).)

The total power spectrum is simply the sum of the contribution from the vacuum fluctuations (64) and the contribution from rescattering (60):

$$P_\phi(k) = P_\phi^{\text{vac}}(k) + P_\phi^{\text{resc}}(k)$$

(70)

There are no cross-terms, owing to the fact $a_k$ and $b_k$ commute.

F. Renormalization

We now wish to evaluate the 2-point correlator (68). In principle, this is straightforward: first substitute the result (60) for the $\chi_k$ modes and the result (69) for the Green function into (68), next evaluate the integrals. However, there is a subtlety. The resulting power spectrum is formally infinite. Moreover, the 2-point correlation function (68) receives contributions from two distinct effects. There is a contribution from particle production, which we are interested in. However, there is also a contribution coming from quantum vacuum fluctuations of the $\chi$ field interacting non-linearly with the inflaton. The latter contribution would be present even in the absence of particle production, when $\alpha_k = 1, \beta_k = 0$.

In order to isolate the effects of particle production on the inflaton fluctuations, we would like to subtract off the contribution to the 2-point correlation function (68) which is coming from the quantum vacuum fluctuations of $\chi$. This subtraction also has the effect of rendering the power spectrum (60) finite, since it extracts the usual UV divergent correlation associated with the Minkowski-space vacuum fluctuations.

As a step towards renormalizing the 2-point correlation function of inflaton fluctuations from rescattering (68), let us first consider the simpler problem of renormalizing the 2-point function of the gaussian field $\chi$. We defined the renormalized 2-point function in momentum space as follows:

$$\langle \xi_{k_1}^\chi(t_1) \xi_{k_2}^\chi(t_2) \rangle_{\text{ren}} = \langle \xi_{k_1}^\chi(t_1) \xi_{k_2}^\chi(t_2) \rangle_{\text{in}} - \langle \xi_{k_1}^\chi(t_1) \xi_{k_2}^\chi(t_2) \rangle_{\text{ren}}$$

(71)

In (71) the quantity $\langle \xi_{k_1}^\chi(t_1) \xi_{k_2}^\chi(t_2) \rangle_{\text{in}}$ is the contribution which would be present even in the absence of particle production, computed by simply taking the solution (69) with $\alpha_k = 1, \beta_k = 0$. Explicitly, we have

$$\langle \xi_{k_1}^\chi(t_1) \xi_{k_2}^\chi(t_2) \rangle_{\text{in}} = \delta^{(3)}(k_1 + k_2) f_{k_1}(t_1) f_{k_2}(t_2)$$

(72)

where $f_k$ are the adiabatic solutions (12).

To see the impact of this subtraction, let us consider the renormalized variance for the iso-inflaton field, $\langle \chi^2 \rangle$. Employing the prescription (71) we have

$$\langle \chi^2(t, \mathbf{x}) \rangle_{\text{ren}} = \int \frac{d^3k}{(2\pi)^3} a^2(\tau) \left| \chi_k(\tau) \right|^2 - \frac{1}{2\omega_k(\tau)}$$

$$= \langle \chi^2(t, \mathbf{x}) \rangle - \delta_M$$

(73)

where $\delta_M$ is the contribution from the Coleman-Weinberg potential. This proves that our prescription reproduces the scheme advocated in [33]. The renormalized variance (73) is finite and may be computed explicitly using our solutions (61). We find

$$\langle \chi^2(t, \mathbf{x}) \rangle_{\text{ren}} \cong \frac{n_\chi a^{-3}}{g|\phi - \phi_0|}$$

(74)

where

$$n_\chi \equiv \int \frac{d^3k}{(2\pi)^3} n_k \sim e^{-\pi T^2/k^2} k^3$$

(75)

is the total co-moving number density of produced $\chi$ particles. The result (73) was employed in [73] to quantify the effect of backreaction on the inflaton condensate in the mean field treatment (11). Hence, the renormalization scheme (71) was implicit in that calculation also.

At the level of the 2-point function, our renormalization scheme is tantamount to assuming that Coleman-Weinberg corrections are already absorbed into the definition of the inflaton potential, $V(\phi)$. In general, such corrections might steepen $V(\phi)$ and spoil slow-roll inflation. Here, we assume that this problem has already been dealt with, either by fine-tuning the bare inflaton potential or else by including extended SUSY (which can minimize dangerous corrections). See also [33] for a related discussion. Note, also, that our renormalization procedure is equivalent to the quasi-particle normal ordering scheme described in [90].

Having established a scheme for renormalizing the 2-point function of the gaussian field $\chi$, it is now straightforward to consider higher order correlation functions.
We simply re-write the 4-point function as a product of 2-point functions using Wick’s theorem. Next, each Wick contraction is renormalized as \[^{14}\]. Applying this prescription to \[^{16}\] amounts to

\[
\langle \xi_{k_1}(\tau) \xi_{k_2}(\tau) \rangle_{\text{ren}} = \frac{2g^2k^4}{(2\pi)^3}\delta^{(3)}(k_1 + k_2)
\]

\[
\times \int d\tau' d\tau'' t(\tau') t(\tau'') a(\tau') a(\tau'') G_{k_1}(\tau - \tau') G_{k_2}(\tau - \tau'')
\]

\[
\times \int d^4k' \left[ \chi_{k_1 - k'}(\tau') \chi_{k_2 - k'}(\tau'') - f_{k_1 - k'}(\tau') f_{k_2 - k'}(\tau'') \right]
\]

\[
\times \left[ \chi_{k'}(\tau') \chi_{k'}(\tau'') - f_{k'}(\tau') f_{k'}(\tau'') \right]
\]

(76)

where \(f_k(t)\) are the adiabatic solutions defined in \[^{12}\].

\[
P_{\phi}^{\text{resc}}(k) = \frac{g^2k^3k_0}{16\pi^3} \left[ \text{e}^{-2\pi\mu^2/k^2} - \text{e}^{-\pi\mu^2/(2k^2)} \right] \left[ I_2(k, \tau) \right] \left[ |I_1(k, \tau)| \right]
\]

\[
+ \left[ \text{e}^{-\pi\mu^2/k^2} - \text{e}^{-\pi\mu^2/(4k^2)} \right] \left[ I_2(k, \tau) - \text{Re} [I_1(k, \tau)] \right]
\]

\[
+ \left[ \frac{8\sqrt{2}}{3\sqrt{3}} \text{e}^{-3\pi\mu^2/(2k^2)} - \text{e}^{-\pi\mu^2/(3k^2)} \right] \left[ I_2(k, \tau) - \text{Im} [I_1(k, \tau)] \right]
\]

(77)

where the functions \(I_1, I_2\) are the curved space generalization of the characteristic integrals defined in \[^{11}\]. Explicitly we have

\[
I_1(k, \tau) = \frac{1}{a(\tau)} \int d\tau' G_k(\tau - \tau') e^{ik^2c^2(\tau')}
\]

(78)

\[
I_2(k, \tau) = \frac{1}{a(\tau)} \int d\tau' G_k(\tau - \tau')
\]

(79)

The characteristic integral \(I_2\) can be evaluated analytically, however, the resulting expression is not particularly enlightening. Evaluation of the integral \(I_1\) requires numerical methods. More details in Appendix A. Equation (77) is the main result of this section.

To test our analytical formalism, let us compare the result (77) with the output of fully nonlinear HLLattice simulations. In Fig. 11 we plot our results for \(P_{\phi}^{\text{resc}}(k)\) as a function of \(k\), for several time steps in the evolution. We have normalized \(P_{\phi}^{\text{resc}}(k)\) to the amplitude of the usual vacuum fluctuations from inflation, \(P_{\phi}^{\text{vac}}(k) \sim H^2/(2\pi)^2\). This figure illustrates the final stages of IR cascading: we see the peak of the bump-like feature slide to \(k \sim e^{-3}k_\star\), at which point the associated mode functions \(\delta\phi_k\) have crossed the horizon and become frozen. At later times in the evolution the peak of the feature and also the IR tail \((\sim k^3)\) remain fixed. Modes associated with the UV end of the spectrum are still inside the horizon and continue to evolve as \(\delta\phi_k \sim a^{-1}\), which explains the damping of the \(k > e^{-2}k_\star\) part of the spectrum. At late times, the shape of the feature that is frozen outside the horizon can be very well approximated by the semi-analytic fitting function \(^{16}\).

The agreement between our analytical formalism and the exact numerical results is quite evident from Fig. 11 and provides a highly nontrivial check on our calculation.

H. The Bispectrum

So far, we have shown how to compute analytically the power spectrum generated by particle production, rescattering and IR cascading in the model \(^{2}\). We found that IR cascading leads to a bump-like contribution to the primordial power spectrum of the inflaton fluctuations. However, this same dynamics must also have a nontrivial impact on nongaussian statistics, such as the bispectrum. Indeed, it is already evident from our previous analysis that the inflaton fluctuations generated by rescattering may be significantly nongaussian. From the expression \(^{68}\) we see that the particular solution (due to rescattering) is bi-linear is the gaussian field \(\chi\).

We define the bispectrum of the inflaton field fluctuations in terms of the three point correlation function as

\[
\langle \xi_{k_1} \xi_{k_2} \xi_{k_3}(\tau) \rangle = (2\pi)^3 a^3(\tau) \delta(k_1 + k_2 + k_3) B_{\phi}(k_i)
\]

(80)
The factor $a^3$ appears in (80) to cancel the explicit factors of $a^{-1}$ in our convention (56) for the Fourier transform. It is well-known that the nongaussianity associated with the usual quantum vacuum fluctuations of the inflaton is negligible (56–58), therefore, when evaluating the bispectrum (80) we consider only the particular solution (68) which is due to rescattering. Carefully carrying out the Wick contractions, we find the following result for the renormalized 3-point function

$$\langle \xi_{k_1}^\phi \xi_{k_2}^\phi \xi_{k_3}^\phi (\tau) \rangle_{\text{ren}} = \frac{4g^3 k^6}{(2\pi)^9} \delta(k_1 + k_2 + k_3) \prod_{i=1}^3 \int d\tau_i \alpha(\tau_i) G_{k_i}(\tau - \tau_i)$$

$$\times \int d^3 p \left[ \chi_{k_1+p}(\tau_1) \chi^*_{k_1}(\tau_2) - f_{k_1+p}(\tau_1) f^*_{k_1+p}(\tau_2) \right] \left[ \chi_{k_3+p}(\tau_2) \chi^*_{k_3+p}(\tau_3) - f_{k_3+p}(\tau_2) f^*_{k_3+p}(\tau_3) \right]$$

$$\times \left[ \chi_p(\tau_1) \chi^*_p(\tau_3) - f_p(\tau_1) f^*_p(\tau_3) \right]$$

$$+ (k_2 \leftrightarrow k_3)$$

where the modes $\chi_k$ are defined by (43) and $f_k$ are the adiabatic solutions (42). On the last line of (81) we have labeled schematically terms which are identical to the preceding three lines, only with $k_2$ and $k_3$ interchanged. One may verify that this expression is symmetric under interchange of the momenta $k_i$ by changing dummy variables of integration.

### I. Estimating the Shape of the Bispectrum

It is straightforward (but tedious) to plug the expressions (50) and (51) into (81) and evaluate the integrals. The resulting expression is extremely cumbersome and not particularly enlightening. We are interested here in extracting some information about the shape of the bispectrum $B_{\phi}(k_i)$. For this purpose, it suffices to work in the flat-space limit, $H \to 0$. This will give a reasonable qualitative picture of the full result since the entire process of IR cascading occurs over a time scale somewhat shorter than the expansion time. In this same approximation was employed to study the power spectrum from IR cascading and was found to reproduce the $H \neq 0$ results to good accuracy.

A detailed calculation of $B_{\phi}(k_i)$ has been relegated to appendix B. Here we simply provide a representative contribution, in order to give a rough sense of the qualitative behaviour:

$$B_{\phi}(k_i) \sim C \prod_{i=1}^3 e^{-\pi k_i^2/(3m^2)} \left[ 1 - \cos \left( \frac{\sqrt{k_i^2 + m^2} t}{k_i^2 + m^2} \right) \right]$$

for some constant $C$. This expression captures some of the qualitative features of the full result, in particular the dynamical cascading of nongaussianity into the IR to generate a localized bispectrum feature. It should be stressed that (82) is a heuristic estimate and not a fit.
ting function nor a systematic approximation to the full result. Hence, equation (52) should not be used to make quantitative predictions of any kind.

As anticipated, our expression for $B_\phi(k_i)$ peaks only over when all wavenumbers are close to the characteristic scale corresponding to the location of the bump in Fig. 10. Therefore, particle production and IR cascading leads to a localized nongaussian feature in the bispectrum, rather than the nearly scale-invariant signatures that are usually considered. We will discuss the phenomenology of this new type of nongaussianity in a forthcoming publication [73].

Now we would like to attempt to characterize the shape of the nongaussianity from particle production and IR cascading. To this end we define a “shape function” $S(k_i)$ as follows

$$S(k_i) = N^{-1}(k_1 k_2 k_3)^2 B_\phi(k_i)$$

where $N$ is a normalization factor which will not concern us. The function $S(k_i)$ has the advantage that the strong $k^6$ running of the bispectrum is extracted. Hence, any residual scaling behaviour displayed by $S(k_i)$ must be a result of nonlinear interactions; see also [51, 52].

Symmetry of the bispectrum under permutations of momenta implies that we can focus only on the region $k_1 \geq k_2 \geq k_3$, to avoid counting the same configuration twice. Moreover, the triangle inequality implies that $1 - \frac{k_3}{k_1} \leq \frac{k_2}{k_1}$. Therefore we can completely specify the shape of the bispectrum for a given size of triangle $k$ by plotting $S(k, kx_2, kx_3)$ in the region $x_3 \leq x_2 \leq 1$ and $1 - x_3 \leq x_2$. (See also [92].) Because our bispectrum is very far from scale-invariant, it follows that this shape function is sensitive to the choice of $k$. Therefore, in Fig. 5 we choose several representative choices: $\ln(k/k_{\text{bump}})$ = $-1, 0, 1, 2$.

We see that a rich array of shape is possible: for $k \geq k_{\text{bump}}$ the bispectrum is qualitatively similar to the equilateral model, however, at slightly larger $k$ there is considerable support on flattened triangles also. Note that for $k \geq 7.4 k_{\text{bump}}$ the shape of the bispectrum is extremely unusual and is not easily comparable to any shape that has been proposed in previous literature.

V. COSMOLOGICAL PERTURBATION THEORY

In section IV we developed an analytical theory of particle production and IR cascading during inflation which is in very good agreement with nonlinear lattice field theory simulations. However, this formalism suffers from a neglect of metric perturbations and, consequently, we were unable to rigorously discuss the gauge invariant curvature perturbation $\zeta$. Hence, the reader may be concerned about gauge ambiguities in our results. In this section we address such concerns, showing that metric perturbations may be incorporated in a straightforward manner and that their consistent inclusion does not change our results in any significant way. We will do so by showing explicitly that, with appropriate choice of gauge, equations (55) and (31) for the fluctuations of the inflaton and iso-inflaton still hold, to first approximation. We will also go beyond our previous analysis by explicitly showing that in this same gauge the spectrum of the curvature fluctuations, $P_\zeta$, is trivially related to the spectrum of inflaton fluctuations, $P_\phi$ (and similarly for the bispectrum).

To render the analysis tractable we would like to take full advantage of the results derived in the last section. To do so, we employ the Seery et al. formalism for working directly with the field equations [92] and make considerable use of results derived by Malik in [94, 95]. (Note that our notations differ somewhat from those employed by Malik. The reader is therefore urged to take care in comparing our formulæ.)

We expand the inflaton and iso-inflaton fields up to

---

9 As we argued in section IV, the size of the nongaussianity in this model is most naturally quantified by evaluating the cumulants. Here we are interested only in discussing the shape of this novel type of nongaussianity.
second order in perturbation theory as

\[ \phi(\tau, x) = \phi(\tau) + \delta \phi(\tau, x) + \frac{1}{2} \delta^2 \phi(\tau, x) \]  

\[ \chi(\tau, x) = \delta \chi(\tau, x) + \frac{1}{2} \delta^2 \chi(\tau, x) \]  

The perturbations are defined to average to zero as

perturbation in terms of annihilation/creation operators

Following our previous analysis we expand the first-order solutions again take the form (63). The explicit factor of \( \delta \) in this gauge the field perturbations \( \delta \phi, \delta \chi \) coincide with the Sasaki-Mukhanov variables \( 94 \) at both first and second order.

A. Gaussian Perturbations

In \( 94 \) Malik has derived closed-form evolution equations for the field perturbations \( \delta \phi, \delta \chi \) at both first \((n = 1)\) and second \((n = 2)\) order in perturbation theory. Let us first study the gaussian perturbations. The closed-form Klein-Gordon equation for \( \delta \phi \) derived in \( 94 \) can be written as

\[ \delta \phi'' + 2H \delta \phi' - \nabla^2 \delta \phi + \left[ a^2 m^2 - 3 \left( \frac{\phi'}{M_p} \right)^2 \right] \delta \phi = 0 \]  

(89)

Following our previous analysis we expand the first-order perturbation in terms of annihilation/creation operators as

\[ \delta \phi(t, x) = \int \frac{d^3 k}{(2\pi)^{3/2}} \left[ b_k \delta \phi_k(\tau) \frac{a}{a(\tau)} e^{ik \cdot x} + \text{h.c.} \right] \]  

(90)

where h.c. denotes the Hermitian conjugate of the preceding term and we draw the attention of the reader to the the explicit factor of \( a^{-1} \) in our definition of the Fourier transform. Working to leading order in slow roll parameters we have

\[ \delta \phi'' + \left[ k^2 + \frac{1}{\tau^2} (-2 + 3\eta - 9\epsilon) \right] \delta \phi = 0 \]  

(91)

This equation coincides exactly with \( 61 \) and the properly normalized solutions again take the form \( 63 \). The only difference is that the order of the Hankel function, \( \nu \), is now given by

\[ \nu \approx \frac{3}{2} - \eta + 3\epsilon \]  

(92)

rather than by equation \( 62 \). The power spectrum of the gaussian fluctuations is, again, given by \( 64 \). The correction to the order of the Hankel function \( \nu \) translates into a correction to the spectral index: instead of \( 65 \) we now have

\[ n_s - 1 = 2\eta - 6\epsilon \]  

(93)

which is precisely the standard result \( 103 \).

Thus, as far as the quantum vacuum fluctuations of the inflaton are concerned, the only impact of consistently including metric perturbations is an \( O(\epsilon) \) correction to the spectral index \( n_s \).

Let us now turn our attention to the first order fluctuations of the iso-inflaton. The closed-form Klein-Gordon equation for \( \delta \chi \) derived in \( 94 \) can be written as

\[ \delta \chi'' + 2H \delta \chi' - \nabla^2 \delta \chi + a^2 \left[ m^2 + k^2 \right] \delta \chi = 0 \]  

(94)

This coincides exactly with equation \( 91 \), which we have already solved. The fact that linear perturbations of \( \chi \) do not couple to the metric fluctuations follows from the condition \( \langle \chi \rangle = 0 \).

B. Nongaussian Perturbations

Now let us consider now the second order perturbation equations. The closed-form Klein-Gordon equation for \( \delta^2 \phi \) derived in \( 94 \) can be written as

\[ \delta^2 \phi'' + 2H \delta^2 \phi' - \nabla^2 \delta^2 \phi + \left[ a^2 m^2 - 3 \left( \frac{\phi'}{M_p} \right)^2 \right] \delta^2 \phi = J(\tau, x) \]  

(95)

As usual, the left-hand-side is identical to the first order equation \( 83 \) while the source term \( J \) is constructed from a bi-linear combination of the first order quantities \( \delta \phi \) and \( \delta \chi \). In order to solve equation \( 85 \) we require explicit expressions for the Green function \( G_k \) and the source term \( J \). The Green function is trivial for the case at hand; it is still given by our previous result \( 62 \), provided one takes into account the fact that the order of the Hankel functions \( \nu \) is now given by \( 62 \), rather than \( 62 \). In other words, the Green function for the nongaussian perturbations \( 85 \) differs from the result obtained neglecting metric perturbations only by \( O(\epsilon) \) corrections.

Next, we would like to consider the source term, \( J \), appearing in \( 85 \). Schematically, we can split the source into contributions bi-linear in the gaussian inflaton fluctuation \( \delta \phi \) and contributions bi-linear in the iso-inflaton \( \delta \chi \):

\[ J = J_\phi + J_\chi \]  

(96)

The contribution \( J_\phi \) would be present even in the absence of the iso-inflaton. These correspond, physically, to the usual nongaussian corrections to the inflaton vacuum
fluctuations coming from self-interactions. This contribution to the source is well-studied in the literature and is known to contribute negligibly to the bispectrum \( \bar{C}_2 \). Thus, in what follows, we will ignore \( J_\phi \).

On the other hand, the contribution \( J_\chi \) appearing in \( \bar{C}_2 \) depends only on the iso-inflaton fluctuations \( \delta_1 \chi \). This contribution can be understood, physically, as generating non-gaussian iso-inflaton fluctuations \( \delta_2 \phi \) by rescattering of the produced \( \chi \) particles off the condensate. Hence, the contribution \( J_\chi \) may source large non-gaussianity and is most interesting for us. It is straightforward to compute \( J_\chi \) explicitly for our model using the general results of \( \text{[4]} \). We find

\[
J_\chi = -2a^2 g^2 (\phi - \phi_0) (\delta_1 \chi)^2 \\
\pm \frac{\sqrt{2} \phi}{M_p} \left[ -a^2 (\mu^2 + g^2 (\phi - \phi_0)^2) (\delta_1 \chi)^2 \\
- \frac{1}{2} (\nabla^2 \delta_1 \chi)^2 - \frac{1}{2} (\delta_1 \chi)^2 \\
+ \nabla^2 \cdot \left( \partial_i (\delta_1 \chi) \nabla^2 \phi (\delta_1 \chi) + \nabla^2 (\delta_1 \chi) \nabla^2 (\delta_1 \chi) \\
+ \delta_1 \chi \nabla^2 \delta_1 \chi + (\nabla \delta_1 \chi)^2 \right) \right]
\]  

(97)

where the upper sign is for \( \phi' > 0 \), the lower sign is for \( \phi' < 0 \). Notice that the contributions to \( J_\chi \) on the fourth and fifth line of \( \text{[97]} \) contain the inverse spatial Laplacian \( \nabla^2 \) and are thus nonlocal. These terms all contain at least as many gradients as inverse gradients and hence the large scale limit is well-defined. In \( \text{[97]} \), it was argued that these terms nearly always contribute negligibly to the curvature perturbation on large scales.

Let us now examine the structure of the iso-inflaton source \( J_\chi \), equation \( \text{[97]} \). The first line of \( \text{[97]} \) goes like \( a^2 g^2 (\phi - \phi_0) (\delta_1 \chi)^2 \). This coincides exactly with the source term in equation \( \text{[55]} \) which was already studied in section \( \text{[IV]} \). On the other hand, the terms on the second, third, fourth and fifth lines of \( \text{[97]} \) are new. These represent corrections to IR cascading which result from the consistent inclusion of metric perturbations. We will now argue that these “extra” terms are negligible as compared to the first line. If we denote the energy density in gaussian iso-inflaton fluctuations as \( \rho_\kappa \sim m^2 (\delta_1 \chi)^2 \), then, by inspection, we see that the first line of \( \text{[97]} \) is parametrically of order \( \rho_\kappa / |\phi - \phi_0| \) while the remaining terms are or order \( \sqrt{\epsilon} \rho_\kappa / M_p \). Hence, we expect the first term to dominate for the field values \( \phi \approx \phi_0 \) which are relevant for IR cascading. This suggests that the dominant contribution to \( J_\chi \) is the term which we have already taken into account in section \( \text{[IV]} \).

Let us now make this argument more quantitative. We assume that \( \mu^2 \ll k^2 \), since otherwise particle production effects are exponentially suppressed. Inspection reveals that the only “new” contribution to \( \text{[97]} \) which has any chance of competing with the “old” term \( a^2 g^2 (\phi - \phi_0) (\delta_1 \chi)^2 \) is the one proportional to \( \sqrt{\epsilon} a^2 g^2 (\phi - \phi_0)^2 (\delta_1 \chi)^2 / M_p \) (on the second line). This new correction has the possibility of becoming significant because it grows after particle production, as \( \phi \) rolls away from \( \phi_0 \). This growth, which reflects the fact that the energy density in the \( \chi \) particles increases as they become more massive, cannot persist indefinitely. Within a few \( e \)-foldings of particle production the iso-inflaton source term must behave as \( J_\chi \sim a^{-3} \), corresponding to the volume dilution of non-relativistic particles. Hence, in order to justify the analysis of section \( \text{[IV]} \) we must check that the term

\[
J_{\text{new}} \sim \frac{\sqrt{\epsilon}}{M_p} a^2 g^2 (\phi - \phi_0)^2 (\delta_1 \chi)^2
\]

(98)
does not dominate over the term which we have already considered

\[
J_{\text{old}} \sim a^2 g^2 (\phi - \phi_0)(\delta_1 \chi)^2
\]

(99)
during the relevant time \( H \Delta t = O(1) \) after particle production. It is straightforward to show that

\[
\frac{J_{\text{old}}}{J_{\text{new}}} \sim \frac{M_p}{\sqrt{\epsilon} \phi_0} \sim \frac{M_p H}{\phi \sqrt{\epsilon}} \sim \frac{1}{\epsilon} \sim \frac{N}{N}
\]

(100)

where \( N = Ht \) is the number of \( e \)-foldings elapsed from particle production to the time when IR cascading has completed. Hence, \( N = O(1) \) and we conclude that the second, third, fourth and fifth lines of \( \text{[97]} \) are (at least) slow roll suppressed as compared to the first line.

In summary, we have shown that consistent inclusion of metric perturbations yields corrections to the inflaton fluctuations \( \delta \phi \) which fall into two classes:

1. Slow-roll suppressed corrections to the inflaton vacuum fluctuations \( \delta_1 \phi \) (these amount to changing the definition of \( \nu \) in the solution \( \text{[63]} \)). These corrections have two physical effects. First, they yield an \( O(\epsilon) \) correction to the spectral index. Second, they modify the propagator \( G_k \) by an \( O(\epsilon) \) correction.

2. Corrections to the source \( J \) for the non-gaussian inflaton perturbation \( \delta_2 \phi \). These corrections are the second, third and fourth lines of \( \text{[97]} \) which, as we have seen, are slow roll suppressed.

It should be clear that neither of these corrections alters our previous analysis in any significant way.

C. Correlators

So far, we have shown that a consistent inclusion of metric perturbations does not significantly alter our previous results for the field perturbations. Specifically, \( \delta_1 \chi \) is identical to our previous solution of equation \( \text{[54]} \) for the iso-inflaton, while \( \delta_1 \phi \) coincides with the homogeneous solution of equation \( \text{[55]} \) up to slow-roll corrections. At second order in perturbation theory, we have seen that

\[
\delta_2 \phi = \int d^4 x' G(x - x') J_\chi(x') + O[(\delta_1 \phi)^2]
\]
To leading order in slow roll $J_\chi \approx -2a^2g_0^2(\phi - \phi_0)(\delta_1 \chi)^2$ and the first term coincides with our previous result for the particular solution of equation [53]. The terms of order $(\delta_1 \chi)^2$ represent nongaussian corrections to the vacuum fluctuations from inflation (coming from self-interactions of $\phi$ and the nonlinearity of gravity). These would be present even in the absence of particle production, and are known to have a negligible impact on the spectrum and bispectrum [92].

We are ultimately interested in the connected n-point correlation functions of $\phi$. For example, the 2-point function $\langle (\delta \phi)^2 \rangle$ get a contribution of the form $\langle (\delta_1 \phi)^2 \rangle$ which gives the usual nearly scale invariant large-scale power spectrum from inflation. The cross term $\langle \delta_1 \phi \delta_2 \phi \rangle$ is of order $\langle (\delta_1 \phi)^4 \rangle$ and represents a negligible “loop” correction to the scale invariant spectrum from inflation. 

The cross term does not involve the iso-inflaton since $\delta_1 \phi$ and $\delta_1 \chi$ are statistically independent.) Finally, there is a contribution $\langle (\delta_2 \phi)^2 \rangle$ which involves terms of order $\langle \chi^4 \rangle$ coming from rescattering and is of order $\langle (\delta_1 \phi)^4 \rangle$ which represent (more) loop corrections to the scale-invariant spectrum from inflation. Thus, we can schematically write

$$P_{\phi}(k) = P_{\phi}^{\text{nc}}(k) [1 + \text{(loops)}] + P_{\phi}^{\text{nc}}(k)$$

Here $P_{\phi}^{\text{nc}} \sim k^{-n_s-1}$ is the usual nearly scale invariant spectrum from inflation and $P_{\phi}^{\text{nc}}$ is the bump-like contribution from rescattering and IR cascading which we have studied in the previous section. The “loop” corrections to $P_{\phi}^{\text{nc}}(k)$ have been studied in detail in the literature (see, for example, [98–101]) and are known to be negligible in most models.

We can also make a similar schematic decomposition of the bispectrum by considering the structure of the 3-point correlator $\langle (\delta \phi)^3 \rangle$. Following our previous line of reasoning, it is clear that the dominant contribution comes from rescattering and is of order $\langle \chi^6 \rangle$. The terms involving $\langle (\delta_1 \phi)^3 \rangle$, on the other hand, represent the usual nongaussianity generated during single field slow roll inflation and are known to be small [92].

**D. The Curvature Perturbation**

Ultimately one wishes to compute not the field perturbations $\delta_\phi$, $\delta_\chi$, but rather the gauge invariant curvature fluctuation, $\zeta$. We expand this in perturbation theory in the usual manner

$$\zeta = \zeta_1 + \frac{1}{2} \zeta_2$$

In [92] Malik has derived expressions for the large scale curvature perturbation in terms of the Sasaki-Mukhanov variables at both first and second order in perturbation theory. We remind the reader that in the flat slicing (which we employ) the Sasaki-Mukhanov variable for each field simply coincides with the field perturbation (i.e. $Q_\phi = \delta \phi$ and $Q_\chi = \delta \chi$).

At first order in perturbation theory the iso-inflaton does not contribute to the curvature perturbation (since $\langle \chi \rangle = 0$) and we have

$$\zeta_1 = -\frac{\mathcal{H}}{\phi} \delta_1 \phi$$

At second order in perturbation theory the expression for the curvature perturbation is more involved. Using the results of [53] and working to leading order in slow roll parameters we find\(^{10}\)

$$\zeta_2 \approx -\frac{\mathcal{H}}{\phi} \left[ \delta_2 \phi - \frac{\delta_2 \phi'}{3\mathcal{H}} \right]$$

$$+ \frac{1}{3(\phi')^2} \left[ (\delta_1 \chi')^2 + a^2 (\mu^2 + g^2 v^2 ) (\delta_1 \chi)^2 \right]$$

$$+ \frac{1}{3(\phi')^2} \left[ (\delta_1 \phi')^2 + a^2 m^2 (\delta_1 \phi)^2 \right]$$

Let us discuss the various contributions to this equation. The third line contributes to the nongaussianity of the vacuum fluctuations during inflation. These terms are known to be negligible [93, 58, 92] and, indeed, one may explicitly verify that (103) would predict $f_{NL} \sim O(\epsilon, \eta)$ in the absence of particle production.

Next, we consider the second line of (103). This represents the direct contribution of the gaussian fluctuations $\delta_1 \chi$ to the curvature perturbation. This contribution is tiny since the $\chi$ particles are extremely massive for nearly the entire duration of inflation and hence $\delta_1 \chi \sim a^{-3/2}$ (see also [2] for a related discussion). The smallness of this contribution to $\zeta$ can be understood physically by noting that the super-horizon iso-curvature fluctuations in our model are negligible.

Finally, let us consider the contribution on the first line of (103). This contribution is the most interesting. To make contact with observations we must compute the curvature perturbation at late times and on large scales. In section [15] we have already shown that $\delta_\phi$ is constant on large scales and at late times for both $n = 1$ and $n = 2$. This is the expected result: the curvature fluctuations are frozen far outside the horizon and in the absence of entropy perturbations. Hence $\delta_2 \phi'$ is completely negligible and the first term on the first line of (103) must dominate over the second term. We conclude that at

\(^{10}\) We have dropped a spurious additive $2\zeta_0^2$ which stems from using the Malik and Wands [102] definition of the curvature perturbation, rather than the definition employed by Lyth and Rodriguez [103] and also by Maldacena [57]. (See also [10].)

\(^{11}\) Note that, in some cases, the curvature fluctuations may evolve significantly after horizon exit [104, 107]. (See also [108].) This is a concern in models where there are significant violations of slow roll. In [1] we have already shown that the transient violation of slow roll has a negligible effect on the curvature fluctuations in our model; see also [2]. Hence, the result $\zeta_1 \sim \delta_0 \phi \sim \text{const}$ far outside the horizon is consistent with previous studies.
late times and on large scales, the second order curvature perturbation is very well approximated by
\[ \zeta_2 \cong -\frac{H}{\phi^2} \delta_2 \phi + \cdots \] (104)

In summary, we have shown that the power spectrum of curvature fluctuations from inflation in the model is trivially related to the power spectrum of inflaton fluctuations
\[ P_\zeta(k) \cong \frac{H^2}{\phi^2} P_\phi(k) = \frac{1}{2\epsilon M_p^2} P_\phi(k) \] (105)

at both first and second order in cosmological perturbation theory. This relation is valid at late times and for scales far outside the horizon. The curvature spectrum may be written as
\[ P_\zeta(k) = P_\zeta^{\text{resc}}(k) [1 + \text{(loops)}] + P_\zeta^{\text{esc}}(k) \] (106)

The power spectrum of the inflaton vacuum fluctuations agrees with the usual result obtained in linear theory
\[ P_\zeta^{\text{resc}}(k) \cong \frac{H^2}{8\pi^2\epsilon M_p^2} \left( \frac{k}{aH} \right)^{2\sigma - 6\epsilon} \] (107)

In (106) we have schematically labeled the corrections arising from the third line of (103) and the source \( J_g \) as “loop”. These are nongaussian corrections to the inflaton vacuum fluctuations arising from self-interactions of the inflaton and also the nonlinearity of gravity. Such corrections are negligible. The most interesting contribution to the power spectrum is due to rescattering, \( P_\zeta^{\text{esc}}(k) \). This quantity is proportional to our previous result (107).

In passing, notice that the bispectrum \( B_\phi \) (defined by (80)) of inflaton fluctuations will differ from the bispectrum \( B \) of the curvature fluctuations (defined by (117)) only by a simple re-scaling:
\[ B(k_i) \cong -\left( \frac{H}{\phi} \right)^3 B_\phi(k_i) = -\frac{1}{(2\epsilon)^{3/2} M_p^3} B_\phi(k_i) \] (108)

The dominant contribution to \( B_\phi \) comes from rescattering effects and scales as \( \langle \delta_2 \phi^3 \rangle \sim \langle \delta_1 \chi^6 \rangle \).

The analysis of this section justifies our neglect of metric fluctuations in section IV.

VI. CONCLUSIONS

In the context of a realistic microscopic framework, we might generically expect the inflaton to couple to a large number of fields whose energy density does not play any important role in driving inflation. Such couplings can lead to isolated bursts of particle production during inflation. The associated observational signatures provide a rare opportunity to learn about how \( \phi \) couples to other species, as opposed to the self-coupling information which is encoded in \( V(\phi) \). In this paper we considered a simple example of this effect which is dynamically rich and derivable from realistic particle physics models, such as string theory.

Inflationary particle production leads to features in the primordial curvature fluctuations via the mechanism of IR cascading. This process is interesting in its own right: it is qualitatively different from other mechanisms in the literature (in that we do not rely on the quantum vacuum fluctuations of some light iso-curvature fields) and the underlying dynamics are relevant for preheating, moduli trapping and non-equilibrium QFT more generally. Moreover, particle production and IR cascading lead to a variety of novel observable signatures, including localized features in both the spectrum and bispectrum of the cosmological fluctuations.

In this paper we have extended previous work on inflationary particle production in two directions. Firstly, we have developed an analytical theory of particle production and IR cascading during inflation, which is in excellent agreement with lattice field theory simulations. This formalism helps to clarify the underlying physics of the mechanism, and provides a crucial cross-check on our numerical methods.

Our second main result has been a more detailed investigation of the nongaussian signature associated with particle production and IR cascading. The bispectrum in this model is rather unusual: it peaks only for triangles with a size comparable to some characteristic scale. We have argued that the magnitude of this type of nongaussianity is best characterized by studying the moments of the PDF. For realistic values of the coupling, the skewness of the PDF is quite large. For example, with \( g^2 \sim 0.01 \) the power spectrum for our model is compatible with all observational data while the skewness of the PDF is equivalent to what would be produced in a local model with \( f_{NL}^{\text{equiv}} \sim -53 \). This value is somewhat larger than current observational bounds, suggesting that nongaussianity from inflationary particle production may be observable in future missions. However, we stress that the nongaussian signature in our model is quite different from what would be expected for a local model with \( \zeta = \zeta_g + \frac{3}{2} f_{NL}^{\text{equiv}} \left[ \zeta_g^2 - \langle \zeta_g^2 \rangle \right] \). In particular, the higher order cummulants (such as the kurtosis) are different, as are the shape and running of the bispectrum.

Note that, if it were to be detected, the nongaussian signature from IR cascading must be correlated with an observable feature in the power spectrum and also with signatures in polarization. Hence, it should be possible to robustly rule out the possibility that massive iso-curvature particles were produced at some point during the observable range of e-foldings of inflation.

The nongaussian signature predicted by inflationary particle production is rather complicated as compared to the local or equilateral models. However, the underlying field theory description of our model is extremely simple and rather generic from the low-energy perspec-
tive. In order to obtain large nongaussianity it was not necessary to fine-tune the inflaton trajectory or appeal to re-summation of an infinite series of high dimension operators. Indeed, the only “tuning” which is required for our signal to be observable is the requirement that \( \phi = \phi_0 \) during the observable range of e-foldings. We believe that this type of nongaussianity is very natural and merits further investigation from the observational perspective.

There are a variety of directions for future studies. From the theoretical perspective, it would be interesting to explicitly generalize our results to more complicated and extensive help with the lattice field theory simulations.

**Acknowledgments**

This work is dedicated to the memory of L. Kofman, who played a key role in initiating this line of research. Thanks to T. Battefeld, I. Huston, K. Malik, M. Sasaki, D. Seery and S. Shandera for helpful discussions, comments and correspondence. I am especially grateful to Z. Huang for numerous discussions, insightful suggestions and extensive help with the lattice field theory simulations.

**APPENDIX A: Detailed Computation of \( P(k) \)**

In this appendix we discuss some of the technical details associated with the computation of the renormalized power spectrum (77). First, notice that using (50) and (51) we can write the quantity appearing in each renormalized Wick contraction as

\[
\chi_k(\tau)\chi_{k'}(\tau') - f_k(\tau)f_k(\tau') \equiv \frac{1}{k^2} \frac{1}{a(\tau)a(\tau')} \frac{1}{\sqrt{t(\tau)t(\tau')}} \left[ n_k \cos \left( \frac{k^2 t^2(\tau)}{2} - \frac{k^2 t^2(\tau')}{2} \right) + \sqrt{n_k} \sqrt{1 + n_k} \sin \left( \frac{k^2 t^2(\tau)}{2} - \frac{k^2 t^2(\tau')}{2} \right) \right] \tag{A-1}\]

where the occupation number \( n_k \) is defined by (49). Plugging (A-1) into (77) we find

\[
P_{\phi}(k) = \frac{g^2 k^3}{8\pi^2} \left[ \int d^3 k' n_{k-k'} n_{k'} \times \int d\tau' d\tau'' \frac{G_k(\tau - \tau') G_k(\tau - \tau'')}{a(\tau)} \cos^2 \left[ \frac{k^2 t^2(\tau')}{2} - \frac{k^2 t^2(\tau'')}{2} \right] \right. \\
+ \int d^3 k' \sqrt{n_{k-k'} n_{k'}} \sqrt{1 + n_{k-k'}} \sqrt{1 + n_{k'}} \left. \times \int d\tau' d\tau'' \frac{G_k(\tau - \tau') G_k(\tau - \tau'')}{a(\tau)} \sin^2 \left[ \frac{k^2 t^2(\tau')}{2} + \frac{k^2 t^2(\tau'')}{2} \right] \right. \\
+ \int d^3 k' \sqrt{n_{k-k'} n_{k'}} \sqrt{1 + n_{k-k'}} \sqrt{n_{k-k'}} \sqrt{1 + n_{k-k'}} \left. \times \int d\tau' d\tau'' \frac{G_k(\tau - \tau') G_k(\tau - \tau'')}{a(\tau)} \cos \left[ \frac{k^2 t^2(\tau')}{2} - \frac{k^2 t^2(\tau'')}{2} \right] \sin \left[ \frac{k^2 t^2(\tau')}{2} + \frac{k^2 t^2(\tau'')}{2} \right] \right] \tag{A-2}\]

Notice that the time and phase space integrations in (A-2) decouple. This is the key simplification which makes an analytical evaluation of this expression tractable. Let us consider these integrations separately.

**A.1. Time Integrals**

All of the integrals over conformal time that appear in (A-2) can be expressed in terms of two characteristic integrals which we call \( I_1 \) and \( I_2 \). Explicitly, these are
defined as

\[ I_1(k, \tau) = \frac{1}{a(\tau)} \int d\tau' G_k(\tau - \tau') e^{ik^2\tau'(\tau')} \quad (A-3) \]

\[ I_2(k, \tau) = \frac{1}{a(\tau)} \int d\tau' G_k(\tau - \tau') \quad (A-4) \]

The second characteristic integral, \( I_2 \), can be evaluated analytically. However, the resulting expression is not particularly enlightening. Evaluation of \( I_1 \), on the other hand, requires numerical methods.

Let us now show how the various integrals appearing in (A-2) may be re-written in terms of \( I_1, I_2 \). First, consider the first line of (A-2) where the following integral appears:

\[
\int d\tau' \int d\tau'' G_k(\tau - \tau') G_k(\tau - \tau'') \cos^2 \left[ \frac{k^2 l^2(\tau')}{2} - \frac{k^2 l^2(\tau'')}{2} \right] \]

\[ = \frac{|I_1(k, \tau)|^2}{2} + \frac{I_2(k, \tau)^2}{2} \quad (A-5) \]

Next, consider the second line of (A-2) where the following integral appears:

\[
\int d\tau' \int d\tau'' G_k(\tau - \tau') G_k(\tau - \tau'') \sin^2 \left[ \frac{k^2 l^2(\tau')}{2} - \frac{k^2 l^2(\tau'')}{2} \right] \]

\[ = - \text{Re} \left[ \frac{I_1(k, \tau)^2}{2} \right] + \frac{I_2(k, \tau)^2}{2} \quad (A-6) \]

Finally, consider the fourth line of (A-2) where the following integral appears:

\[
\int d\tau' \int d\tau'' G_k(\tau - \tau') G_k(\tau - \tau'') \cos \left[ \frac{k^2 l^2(\tau')}{2} - \frac{k^2 l^2(\tau'')}{2} \right] \sin \left[ \frac{k^2 l^2(\tau')}{2} + \frac{k^2 l^2(\tau'')}{2} \right] \]

\[ = \text{Im} I_1(k, \tau) I_2(k, \tau) \quad (A-7) \]

A.2. Phase Space Integrals

As a warm-up to the subsequent calculation consider the following integral:

\[
\int d^3k' n_{k-k'}^a n_{k'}^b \]

\[ = \int d^3k' \exp \left[ -a|k-k'|^2/k^2 \right] \exp \left[ -b|k'|^2/k^2 \right] \]

\[ = \frac{k^3}{(a+b)^{3/2}} \exp \left[ -\pi(a+b)k^2 \right] \]

\times \exp \left[ -\pi k^2 \right] \quad (A-8) \]

This formula is valid when \( a, b \) are positive real numbers. Notice that this expression is symmetric under interchange of \( a \) and \( b \).

The phase space integral in the first line of (A-2) is computed by a trivial application of the identity (A-8):

\[
\int d^3k' n_{k-k'} n_{k'} \sqrt{1+n_{k'}} \sqrt{1+n_{k'}} \]

\[ \approx \int d^3k' \left[ n_{k-k'}^{1/2} n_{k'}^{1/2} + \frac{1}{2} n_{k-k'}^{1/2} n_{k'}^{1/2} + \frac{1}{2} n_{k-k'}^{1/2} n_{k'}^{1/2} \right] \]

\[ = k^3 \left[ e^{-\pi\mu^2/k^2} \exp \left( -\frac{\pi k^2}{4k^2} \right) + e^{-\pi\mu^2/k^2} \exp \left( -\frac{3\pi k^2}{8k^2} \right) \right] \quad (A-9) \]

Finally, consider the phase space integral on the third line of (A-2):

\[
\int d^3k' \left[ n_{k-k'} \sqrt{1+n_{k'}} \sqrt{1+n_{k'}} \right] \approx \int d^3k' \left[ n_{k-k'}^{1/2} n_{k'}^{1/2} + \frac{1}{2} n_{k-k'}^{1/2} n_{k'}^{1/2} + \frac{1}{2} n_{k-k'}^{1/2} n_{k'}^{1/2} \right] \]

\[ = k^3 \left[ \frac{4\sqrt{2}}{3\sqrt{3}} e^{-3\pi\mu^2/(2k^2)} \exp \left( -\frac{\pi k^2}{3k^2} \right) + \frac{2\sqrt{2}}{3\sqrt{3}} e^{-5\pi\mu^2/(2k^2)} \exp \left( -\frac{3\pi k^2}{5k^2} \right) \right] \quad (A-10) \]

We have verified the formulae (A-10,A-11) numerically. In both cases that the numerical results agree with these semi-analytical expressions up to the percent level.

We can now, finally, insert the results (A-5,A-6,A-7) into the expression (A-2). Doing so, we arrive at our main analytical result, which is equation (77).

APPENDIX B: Evaluation of the Bispectrum

In this appendix we discuss some of the technical details associated with the explicit evaluation of the
For defined by (78) and (79) can be computed analytically. Let the 2-point function, the phase space and time integrals decouple, making an analytical evaluation tractable. Let $I_1(k, t), I_2(k, t)$ defined by (78) and (79) can be computed analytically. For $I_1(k, t)$ we find

\[ I_1(k, t) = \frac{\sqrt{\pi}}{2k_\mu} e^{i\Omega t - \Omega_1^2/(4k^2)} e^{-\pi/4} F(k, t) \]

(B-2)

\[ F(k, t) = \frac{1}{2} \left[ (1 + e^{-2i\Omega t}) \text{erf} \left( \frac{e^{-i\pi/4} \Omega_{k_\mu}}{2k_\mu} \right) \right. \]

(B-3)

\[ - \text{erf} \left( \frac{e^{-i\pi/4} \Omega_{k_\mu}}{2k_\mu} - 2k_\mu t \right) \]

\[ - e^{-2i\Omega t} \text{erf} \left( \frac{e^{-i\pi/4} \Omega_{k_\mu}}{2k_\mu} + 2k_\mu t \right) \]

\[ \right. \]

while, for $I_2(k, t)$, we have

\[ I_2(k, t) = \frac{1}{\Omega_{k_\mu}} [1 - \cos(\Omega_{k_\mu} t)] \] (B-4)

(Note that our definition of $I_1, I_2$ differs from [1] by a factor of $\Omega_{k_\mu}^{-1}$.) Finally, the renormalized Wick contraction (A-1) also simplifies in the limit $H \to 0$:

\[ \chi_k(t) \chi_k(t') - f_k(t) f_k(t') \equiv \]

\[ \frac{1}{k_\mu^2 \sqrt{i\mu'}} \left[ n_k \cos \left( \frac{k_\mu^2 t^2}{2} - \frac{k_\mu^2 (t')^2}{2} \right) \right. \]

\[ + \sqrt{n_k} \sqrt{1 + n_k} \sin \left( \frac{k_\mu^2 t^2}{2} - \frac{k_\mu^2 (t')^2}{2} \right) \] (B-5)

where the occupation number $n_k$ is defined by (10).

Inserting (B-1) and (B-5) into (81) we find the following expression for the renormalized 3-point correlation function:

\[ \langle \phi_{k_1} \phi_{k_2} \phi_{k_3} \rangle(t) = \frac{4g^3}{(2\pi)^9/2} \delta^{(3)}(k_1 + k_2 + k_3) \prod_{j=1}^{3} \int \frac{d\Omega_{k_j}}{\Omega_{k_j}} \sin \Omega_{k_j} (t - t_j) \]

\[ \times \int d^3 p \left[ n_{k_1 - p} \cos \left( \frac{(k_1 t_1)^2}{2} - \frac{(k_2 t_2)^2}{2} \right) + n_{k_1 - p} \sqrt{1 + n_{k_1 - p}} \sin \left( \frac{(k_1 t_1)^2}{2} + \frac{(k_2 t_2)^2}{2} \right) \right. \]

\[ \times \left. \left. n_{k_3 + p} \cos \left( \frac{(k_3 t_3)^2}{2} - \frac{(k_2 t_2)^2}{2} \right) + n_{k_3 + p} \sqrt{1 + n_{k_3 + p}} \sin \left( \frac{(k_3 t_3)^2}{2} + \frac{(k_2 t_2)^2}{2} \right) \right] \right. \]

\[ \times \left. \left. n_p \cos \left( \frac{(k_4 t_4)^2}{2} - \frac{(k_3 t_3)^2}{2} \right) + n_p \sqrt{1 + n_p} \sin \left( \frac{(k_4 t_4)^2}{2} + \frac{(k_3 t_3)^2}{2} \right) \right] \right. \]

(B-6)

It only remains to expand out the expression (B-6) and evaluate the various integral which arise. As in the case of the 2-point function, the phase space and time integrals decouple, making an analytical evaluation tractable. Let us consider the various integrals which arise separately.

### B.1. Phase Space Integrals

First, let us introduce a notation for the fundamental phase space integral which arises

\[ K_{a,b,c} = \int d^3 p \ n_{k_1 - p} n_{k_2 + p} n_{k_3 + p} \exp \left( \frac{-\pi (a + b + c) k_p^2}{k_\mu^2} \right) \]

\[ \times \exp \left( -\frac{\pi (a k_\mu^2 + b k_\mu^2 + a b k_\mu^2)}{k_\mu^2 (a + b + c)} \right) \]

(B-7)

where we have used the fact that $k_1 + k_2 + k_3 = 0$. To evaluate integrals containing radicals such as $\sqrt{1 + n_p}$ we use the same trick as was employed for (A-10). That is,
we approximate:

\[
\int d^3p \, n_{k_1-p} n_{k_3+p} n_p^{3/2} \sqrt{1+n_p} \\
\approx \int d^3p \, n_{k_1-p} n_{k_3+p} n_p^{1/2} + \frac{1}{2} \int d^3p \, n_{k_1-p} n_{k_3+p} n_p^{3/2} \\
= K_{1,1,1/2} + \frac{1}{2} K_{1,1,3/2}
\]

(B-8)

and similarly for the other combinations which arise in the expansion of \[\text{[B-6]}\]. We have checked numerically that this gives a good approximation to the exact result.

### B.2. Time Integrals

The evaluation of the time integrals appearing in \[\text{[B-6]}\] is a straightforward generalization of the results presented in appendix A. Let us introduce some notations for the various combinations of the fundamental integrals \(I_1\) and \(I_2\) that will appear in the final result:

\[
A = \prod_j \int \frac{dt_j}{\Omega_{k_j}} \sin(\Omega_{k_j}(t - t_j)) \times \cos \left( \frac{(k_1t_1)^2 - (k_2t_2)^2}{2} \right) \cos \left( \frac{(k_2t_2)^2 - (k_3t_3)^2}{2} \right) \cos \left( \frac{(k_3t_3)^2}{2} - \frac{(k_3t_3)^2}{2} \right)
\]

(B-9)

\[
B = \prod_j \int \frac{dt_j}{\Omega_{k_j}} \sin(\Omega_{k_j}(t - t_j)) \times \sin \left( \frac{(k_1t_1)^2 + (k_2t_2)^2}{2} \right) \sin \left( \frac{(k_2t_2)^2 + (k_3t_3)^2}{2} \right) \sin \left( \frac{(k_3t_3)^2}{2} + \frac{(k_3t_3)^2}{2} \right)
\]

(B-10)

\[
C_1 = \prod_j \int \frac{dt_j}{\Omega_{k_j}} \sin(\Omega_{k_j}(t - t_j)) \times \cos \left( \frac{(k_1t_1)^2 - (k_2t_2)^2}{2} \right) \cos \left( \frac{(k_2t_2)^2 - (k_3t_3)^2}{2} \right) \sin \left( \frac{(k_3t_3)^2}{2} + \frac{(k_3t_3)^2}{2} \right)
\]

(B-11)

\[
C_2 = \prod_j \int \frac{dt_j}{\Omega_{k_j}} \sin(\Omega_{k_j}(t - t_j)) \times \sin \left( \frac{(k_1t_1)^2 + (k_2t_2)^2}{2} \right) \sin \left( \frac{(k_2t_2)^2 + (k_3t_3)^2}{2} \right) \cos \left( \frac{(k_3t_3)^2}{2} - \frac{(k_3t_3)^2}{2} \right)
\]

(B-12)

\[
C_3 = \prod_j \int \frac{dt_j}{\Omega_{k_j}} \sin(\Omega_{k_j}(t - t_j)) \times \sin \left( \frac{(k_1t_1)^2 + (k_2t_2)^2}{2} \right) \sin \left( \frac{(k_2t_2)^2 + (k_3t_3)^2}{2} \right) \cos \left( \frac{(k_3t_3)^2}{2} - \frac{(k_3t_3)^2}{2} \right)
\]

(B-13)

\[
D_1 = \prod_j \int \frac{dt_j}{\Omega_{k_j}} \sin(\Omega_{k_j}(t - t_j)) \times \cos \left( \frac{(k_1t_1)^2 - (k_2t_2)^2}{2} \right) \sin \left( \frac{(k_2t_2)^2 + (k_3t_3)^2}{2} \right) \cos \left( \frac{(k_3t_3)^2}{2} + \frac{(k_3t_3)^2}{2} \right)
\]

(B-14)

\[
D_2 = \prod_j \int \frac{dt_j}{\Omega_{k_j}} \sin(\Omega_{k_j}(t - t_j)) \times \sin \left( \frac{(k_1t_1)^2 + (k_2t_2)^2}{2} \right) \cos \left( \frac{(k_2t_2)^2 - (k_3t_3)^2}{2} \right) \sin \left( \frac{(k_3t_3)^2}{2} + \frac{(k_3t_3)^2}{2} \right)
\]

(B-15)

\[
D_3 = \prod_j \int \frac{dt_j}{\Omega_{k_j}} \sin(\Omega_{k_j}(t - t_j)) \times \sin \left( \frac{(k_1t_1)^2 + (k_2t_2)^2}{2} \right) \sin \left( \frac{(k_2t_2)^2 + (k_3t_3)^2}{2} \right) \cos \left( \frac{(k_3t_3)^2}{2} - \frac{(k_3t_3)^2}{2} \right)
\]

(B-16)
B.3. The Full Bispectrum

We are now finally in a position to write out an explicit expression for the renormalized 3-point function of the inflaton fluctuations generated by IR cascading.

That expression is given below, in terms of the various that were defined explicitly in equations (B-15) and (B-16). As promised, the explicit result for the 3-point correlation function is cumbersome and not entirely enlightening.

\[
\langle \xi_{k_1}^{\phi} \xi_{k_2}^{\phi} \xi_{k_3}^{\phi}(t) \rangle = \frac{4g^3}{(2\pi)^{9/2}} \delta^{(3)}(k_1 + k_2 + k_3) \left[ K_{1,1,1}A + \left[ K_{1/2,1/2,1/2} + \frac{1}{2} \left( K_{3/2,1/2,1/2} + K_{1/2,1/2,3/2} + K_{1/2,1/2,3/2} \right) \right] B 
+ \left[ K_{1,1,1} + \frac{1}{2} K_{1,1,3} \right] C_1 + \left[ K_{1,1,2} + \frac{1}{2} K_{3,2,1} \right] C_2 + \left[ K_{1,2,1,1} + \frac{1}{2} K_{3,2,1,1} \right] C_3 
+ \left[ K_{1,2,1,2} + \frac{1}{2} \left( K_{3,1,2,2} + K_{1,2,3,2} \right) \right] D_1 + \left[ K_{1,2,1,1} + \frac{1}{2} \left( K_{3,2,1,1} + K_{1,2,3,2} \right) \right] D_2 
+ \left[ K_{1,2,1,2} + \frac{1}{2} \left( K_{3,2,1,2} + K_{1,2,3,1} \right) \right] D_3 + (k_2 \leftrightarrow k_3) \right] \] (B-17)
