(Dated: July 26, 2005)

The possibility of Cherenkov-like gluon bremsstrahlung in dense matter is studied. We point out that the occurrence of Cherenkov radiation in dense matter is sensitive to the presence of partonic bound states. This is illustrated by a calculation of the dispersion relation of a massless particle in a simple model in which it couples to two different massive resonance states. We further argue that detailed spectroscopy of jet correlations can directly probe the index of refraction of this matter, which in turn will provide information about the mass scale of these partonic bound states.

The goal of high-energy heavy-ion collisions is to create and explore a novel state of matter in which quarks and gluons are deconfined over distances considerably larger than that of a hadron. Lattice QCD calculations have predicted such a transition with a rapid rise in the entropy density at a critical temperature of about $T_c \approx 170$ MeV. However, the entropy density is seen to level off somewhat below the ideal gas limit. Calculations with a more sophisticated resummation of quasiparticle modes within the hard-thermal-loop approximation improve upon the ideal gas picture but are still above the lattice QCD results near and just above $T_c$, suggesting that the plasma may possess a somewhat more complex structure in this regime. Indeed, recent lattice QCD calculations of spectral functions find the presence of charmonium states above $T_c$. This has led to the suggestion that at moderate temperatures, $T \approx 1 - 2 T_c$, there exist many bound states both in the color singlet and other colored representations, though lattice QCD results on baryon-strangeness correlations can rule out the presence of many light bound states involving only quarks and anti-quarks. Furthermore, strong collective flow observed in experiments at the Relativistic Heavy-Ion Collider (RHIC) also suggest a strongly interacting plasma. Therefore, the nature of the relevant degrees of freedom in the matter created at RHIC needs to be further explored.

It is the purpose of this Letter to argue and demonstrate that one can probe the resonance structure of the dense matter via the production of Cherenkov-like soft hadrons along the path of quenched jets. Jet quenching or medium modification of the jet structure has emerged as a new diagnostic tool for the study of partonic properties of the dense matter. The modification goes beyond a mere suppression of inclusive spectra of leading hadrons and has been extended to include the modification of two-hadron correlations. Of particular interest for the present work is the experimental observation that soft hadrons correlated with a quenched jet have an angular distribution that is peaked at a finite angle away from the jet, whereas they peak along the jet direction in vacuum. In the picture of normal gluon bremsstrahlung induced by multiple parton scattering, one can identify these associated soft hadrons with those from the hadronization of radiated gluons. Because of the Landau-Pomeranchuk-Migdal (LPM) interference, the angular distribution of the induced gluon bremsstrahlung does peak at an angle $\theta \approx \sqrt{2/\omega_g L}$ away from the initial jet direction. However, this angle decreases with the length of the jet propagation or with the centrality of the nuclear collisions. This is currently not supported by the experimental data.

Two other known phenomena can, however, result in such an emission pattern: Mach cones generated by the hydrodynamical propagation of energy deposited by a quenched jet along its path and Cherenkov gluon radiation. The angle of particle emission from the generated Mach cone is determined by the velocity of sound which can be calculated in lattice QCD. In the case of Cherenkov gluon radiation, the situation is less clear. While the general phenomenon has been discussed, the essential question, whether the index of refraction, which determines the cone angle, is larger than unity in deconfined QCD matter has not been addressed. Indeed, calculations in the Hard Thermal Loop (HTL) approximation of QCD do not allow for Cherenkov gluon radiation. Quenched lattice QCD calculations also indicate a time-like dispersion relation for large momenta ($p >> T$) at $T > T_c$. The situation, however, is unclear for soft modes $p < T$ and at around $T_c$.

In this Letter, we start with the realization that a large index of refraction and therefore Cherenkov-like gluon bremsstrahlung can only result from coherent gluon scattering off partonic bound states in the QGP. The situation is analogous to photons in a gas, where the coherent scattering off atoms in the gas allows for Cherenkov radiation, but not in a gas of single elementary charged particles. Thus the observation of Cherenkov-like bremsstrahlung in heavy-ion collisions would serve as an signal for the presence of bound states in the QGP.

Obviously, a large index of refraction, corresponding to a space-like dispersion relation, requires attractive interaction. This is where the bound states enter the picture: It is natural to assume that these bound states
have excitations, just like an atom, and gluon interaction can cause transition between these bound states through simple resonant scattering. If the energy of the gluon is smaller than that of the first excited state, the scattering amplitude is attractive leading to an attractive optical potential for such a gluon. As a consequence, the gluon dispersion relation in this regime becomes space-like and Cherenkov radiation will occur. Similar effects have been noted in the context of gluon scattering in nuclei [27] or pion scattering in nuclear matter, where the transition of the nucleon to the Delta resonance provided the necessary attraction [28].

**FIG. 1:** The general contribution to the self-energy of $\Phi$ due to transitional interaction.

To illustrate this effect within finite temperature field theory, a simplified model is employed: a massless scalar $\Phi$ (representing the radiated gluon) coupled to two massive scalars $\phi_1, \phi_2$, representing a bound state and its excitation. The interaction is such that $\Phi$ may induce a transition from $\phi_1$ to $\phi_2$ and vice-versa. The Lagrangian for such a system, ignoring the self-interactions between the scalars, has the form

$$L = \sum_{i=1}^{2} \left( \frac{1}{2} \partial^2 \phi_i + \frac{1}{2} \partial^2 \phi_2 + g^2 \phi_1 \phi_2 \phi_3 \right).$$  \hspace{1cm} (1)

The coupling constant $g$ is dimensionful; this along with all other scales in this Letter will be expressed in units of the temperature. Ignoring issues related to vacuum renormalizability of such a theory, we focus on a study of the dispersion relation of the massless scalar in such an environment. The thermal propagator of $\Phi$ in the interacting theory is given in general as

$$D(p^\beta, \vec{p}) = \frac{1}{(p^\beta)^2 - [\vec{p}]^2 - \Pi(p^\beta, \vec{p}, T)},$$ \hspace{1cm} (2)

and the dispersion relation is given by the on-shell condition: $(p^\beta)^2 - [\vec{p}]^2 - \Pi(p^\beta, \vec{p}, T) = 0$. Here, $\Pi(p^\beta, \vec{p}, T)$ is the thermal self-energy of $\Phi$ due to loop diagrams such as the one shown in Fig 2. The imaginary parts of this self-energy at finite temperature has been discussed in Ref. [29]. In this Letter, the focus will be on the real part of the one-loop self-energy.

In order to discuss the the essential contributions to the self-energy, it is decomposed, following Ref. [27], as:

$$\Pi(p^\beta, \vec{p}) = g^2 \int \frac{d^3k}{(2\pi)^3} \frac{1}{2} \left[ \frac{1}{2E_1(\vec{k})} \left\{ \left[ 1 + n(E_1(\vec{k})) \right] + \left[ n(E_1(\vec{k})) \right] \right\} \right] (3)$$

$$+ \frac{1}{2E_1(\vec{k})} \left\{ \left[ 1 + n(E_1(\vec{k})) \right] + \left[ n(E_1(\vec{k})) \right] \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\} \left[ \vec{p}^2 - E_1(\vec{k})^2 \right] - E_2(\vec{p} + \vec{k}) \right\},$$

where, $n(E)$ denotes the thermal (Bose-Einstein) distribution. In the subsequent discussion, only the temperature dependent parts of the self-energy, i.e., those terms involving thermal distributions, are relevant. In the case when $m_2 - m_1 \gg T$, the last two terms are suppressed by Boltzmann factors as compared to the first two. In the above equation, the first term represents the standard resonant scattering contribution, where the “gluon”, $\Phi$, absorbs the lower bound state, $\phi_1$, and propagates through the space-like off-shell intermediate state $\phi_2$. At low gluon momenta $p$, this is the dominant term which provides the necessary attraction. In Fig 2 the real and imaginary parts of the self-energy are plotted as functions of the energy for a fixed momentum $p^\beta = 1.5T$, $m_1 = T$, $m_2 = 3T$ and $g = 2T$. Contributions to the real part from the first two terms which are the dominant contributions are also plotted. Note that at low energies, below the resonance $(s \equiv \vec{p}^2 - p^\beta = (m_2 - m_1)^2)$, we find attraction as expected from resonance scattering. At higher energies, just before the threshold $(s = (m_1 + m_2)^2)$ for the production of a pair of $\phi_1, \phi_2$ states, additional attraction is also found for the given four-momentum. This corresponds to the emission of a $\phi_2$ by $\Phi$ and creation of an space-like off-shell $\phi_2$. This region, however, is not relevant for the subsequent discussion of Cherenkov radiation.

In principle, one should include the contribution from the self-coupling of $\Phi$ to the self energy. For vector gluons, such a contribution, in isolation, gives rise to a time-like dispersion relation, and in combination with the gluon-resonance coupling may lead to a complicated momentum dependence of the dispersion relation. However, if the gluon-resonance coupling is much stronger than the gluon self-coupling, one may neglect such a contribution to the self-energy.

The resulting dispersion relations for different choices of masses of $\phi_1, \phi_2$ are shown in Fig 3. As expected we obtain a space-like dispersion relation in low momentum
which approaches the light-cone as \((p^0, \vec{p})\) is increased. Even though we have studied a simple scalar theory, the attraction leading to Cherenkov-like bremsstrahlung has its origin in resonant scattering. Thus, the result is genuine and only depends on the masses of the bound states and their excitations.

\[ m_1 = 1T, m_2 = 3T \]
\[ m_1 = 0.5T, m_2 = 3T \]
\[ m_1 = 0.5T, m_2 = 1T \]

Another essential issue is the behavior of the imaginary part of the self-energy along the curve of the quasiparticle dispersion relation. The imaginary parts are always found to be negative, which in our convention indicates damping of the modes. In Fig. 3, we plot the real and imaginary parts of the self-energies for values of \((p_0, \vec{p})\) which satisfy the in-medium dispersion relation.

\[ \frac{dE}{dx} = 4\pi\alpha_s \int_{n(p_0)>1} p_0 \left[ 1 - \frac{1}{n^2(p_0)} \right] dp_0, \quad (4) \]
where \( n(p_0) = |\vec{p}|/p_0 \) is the index of reflection. Using the dispersion relation in our simple model, the typical energy scale for the soft mode where Cherenkov radiation can happen is \( p_0 \sim T \). The Cherenkov energy loss is about \( dE/dx \sim 0.1 \text{ GeV/fm} \) for \( T \sim 300 \text{ MeV} \). This is much smaller than the normal radiative energy loss induced by multiple scattering of the energetic partons \( \gamma \). As discussed in Ref. 10, bremsstrahlung, induced by multiple scattering, of soft gluons with a space-like dispersion relation can still lead to Cherenkov-like angular distributions due to Landau-Pomeranchuck-Migdal interference. Such Cherenkov-like gluon bremsstrahlung will lead to a similar emission pattern of soft hadrons as pure Cherenkov radiation. Thus, a distinctive experimental signature of the Cherenkov-like gluon radiation is the strong momentum dependence of the emission angle of soft hadrons leading to the disappearance of a cone-like structure for large \( p_T \) associated hadrons.

In conclusion, we have shown how bound states in the QGP or more generally additional mass scales give rise to radiation of Cherenkov gluons off a fast jet traversing the medium. These Cherenkov gluons lead to a cone-like emission pattern of soft hadrons. The cone angle with respect to the jet direction exhibits a strong momentum dependence in contrast to a Mach-cone. Pure Cherenkov radiation leads to energy loss which, however, is too small to account for the jet suppression observed in RHIC experiments. Collision-induced Cherenkov-like bremsstrahlung \( \gamma \) can explain both the observed energy loss and the emission pattern of soft hadrons in the direction of quenched jets.
