Abstract

For the first time an all optical flip-flop is demonstrated based on two coupled Mach-Zehnder interferometers which contain semiconductor optical amplifiers in their arms. The flip-flop operation is discussed and it is demonstrated using commercially available fiber pigtailed devices. Being based on Mach-Zehnder interferometers, the flip-flop has potential for very high speed operation.

I. Introduction

Optical bistable devices and in particular all optical flip-flops can have many uses in optical telecommunications and computing such as: threshold functions, 3R regeneration, de-multiplexing and rate conversion of telecommunication data [1].

All optical flip-flops based on two coupled devices provide many advantages such as controllable behaviour, separate set/reset inputs and identical set/reset operations, and large input wavelength range. Such a flip-flop using two coupled lasers was demonstrated and analyzed in [2]. In particular, the function of light output by a laser versus the light injected into a laser has the correct characteristics so that when two lasers are coupled the following occurs: The system has more than one steady state solution, and at least two of the steady state solutions are stable states of the system.

Integrated Mach-Zehnder interferometers (MZI) incorporating semiconductor optical amplifiers (SOA) in the interferometer arms have recently been developed as very high speed all optical switching devices [3],[4]. The function of light output by a MZI (with a constant bias light injected) versus the light injected into the MZI, can also have the correct characteristics for forming an all optical flip-flop. In this paper we experimentally demonstrate for the first time an all optical flip-flop based on two coupled MZI (with SOAs in their arms).

II. Operating Theory

The structure of the flip-flop is shown in Figure 1. It consists of two MZIs (MZI 1 and MZI 2) and a SOA connecting the two. The connecting SOA provides a controllable gain between the two MZIs. For the moment assume that the SOA gain is one and that it can be replaced with a direct optical connection between MZI 1 and MZI 2. Each MZI has a continuous wave (CW) bias light input $S_{bias}$.

Qualitatively the flip-flop functions as follows: With the flip-flop in state 1 light out of MZI 1 flows into the SOA of MZI 2, changing gain and refractive index such that much less light exits from MZI 2 and flows back into MZI 1.
State 2 is the reverse case where a large amount of light flows out of MZI 2 suppressing light flowing out of MZI 1 and back into MZI 2.

To switch the flip-flop between state 1 or 2 light can be injected into the MZI that dominates (that is the one injecting the most light into the other MZI), via the In 1 or In 2 ports (Figure 1). The injected light reduces the light exiting the dominate MZI, which allows the suppressed MZI to increase its light output and become the dominate MZI.

The flip-flop can be described quantitatively as follows. Each MZI can be modeled with: a rate equation for the carrier number of the SOA in its arms [5],[2], an equation relating carrier changes to refractive index and phase changes [6], and an equation to model the recombining of the signals in the arms at the MZI output coupler [4]. $S_{out1}$ as a function of $S_{in1}$ or equivalently $S_{out2}$ can be found for the steady state from the MZI model for a particular set of operating conditions. One of these functions of $S_{out1}$ versus $S_{out2}$ is plotted in Figure 2. The SOA parameters used to construct the plot were from [6] (with the additional parameters of intrinsic losses $\alpha_{int} = 27 \text{ cm}^{-1}$ and group velocity in the SOA $\nu_g = 8 \times 10^9 \text{ cm s}^{-1}$).

Also plotted in Figure 2 is $S_{out2}$ as a function of $S_{out1}$. The points where the two curves intersect represent steady state solutions for the system of two MZIs. The point labelled B1 represents state 1 mentioned above. Point B2 represents state 2. Both B1 and B2 can be shown to be stable states of the system [2]. The point S represents a state where the same amounts of light flow from MZI 1 to MZI 2 and visa versa, however it is not a stable state of the system [2].

### III. Experiment

To demonstrate the all optical flip-flop just described above the setup show in Figure 1 was realized using commercially available SOAs and fiber based couplers. The SOAs employed a strained bulk active region and were manufactured by JDS-Uniphase.
The central SOA was not necessary from a theoretical standpoint. However it allowed the coupling between the MZIs to be varied as was necessary to obtain strong bistable operation.

The amount of light being injected into each MZI 1 and MZI 2 was measured by a photodiodes PD 1 and PD 2, Figure 1. To toggle the flip-flop between states light pulses of power 3.3 mW, wavelength 1547 nm, and duration 5 ms were regularly injected into the inputs In 1 and In 2 (Figure 1). The CW bias light power was 1.25 mW, and had wavelength 1552 nm for MZI 1 and 1550 for MZI 2. The MZI SOA currents were such that with only the CW bias light injected into them they had a gain of 10.

The inputs pulses were injected every 50 ms into alternate MZIs. The changing of state of the flip-flop every 50 ms can be clearly seen in Figure 3, demonstrating proper flip-flop operation. Also the effects of the 5 ms input pulses can be seen.

IV. Conclusions

In this paper we have shown that it is possible to make an all optical flip-flop out of two Mach-Zehnder interferometers (with non-linear elements in their arms, here SOAs). Integrated versions of the flip-flop could operate at very high speeds [3], [4], as the MZIs themselves respond quickly and they are located close to each other. Furthermore the integrated MZIs will be stable. The use of MZIs makes the flip-flop presented here inherently faster than the flip-flop presented in [2] that is based on couplers lasers. The attributes of high speed and potentially wide input wavelength range would make the flip-flop suitable for all optical signal processing applications in high-speed telecommunications.

Other arrangements of the MZIs apart from that shown in Figure 1 are possible. For example it is possible to remove the SOA between the MZIs and share a common coupler between the MZIs. Additional couplers could be added in the MZIs for inputs or outputs. Finally the concept of optically bistable coupled MZIs could prove useful for increasing the sensitivity of MZI based optical sensors.
