ANKYLOSING spinal disorders (ASDs) such as ankylosing spondylitis (AS) and diffuse idiopathic skeletal hyperostosis (DISH) are complex diseases, especially when it comes to surgical treatment in cases of trauma.

AS is a seronegative systemic chronic rheumatic disease. It mainly manifests in the axial skeleton, especially the spine. It is characterized by disruption of bone architecture combined with osteoplastic changes. This results in osteoporosis of the spine with a further increased risk of fractures.\(^1\) As the disease progresses, complete stiffening of the spine occurs along with increased thoracic kyphosis and lumbar lordosis.

DISH is a skeletal disorder presented with skeletal hyperostosis such as abundant formations of bone, especially of the anterior longitudinal ligament, and is mostly found in male patients aged 50 years or older.\(^2,3\) It ultimately results in progressive stiffening of the spine, causing pain, stiffness, and dysphagia.\(^4\) While dual-energy x-ray absorptiometry often suggests higher bone mineral density (BMD), studies including quantitative CT have shown no increase in BMD in patients with DISH.\(^5\) Furthermore, pa-
Patients with low BMD and DISH are even more likely to incur vertebral fractures. Due to reduced flexibility and a strong cantilever in each direction, those patients experience fractures more frequently, and treatment requires longer constructs to address the long cantilevers.

In cases of trauma, diagnostics and treatment strategies in these patients are often unclear. A change in biomechanics of the ossified spine requires extensive diagnostics. Regarding treatment, patients show high complication rates as well as high mortality rates. However, fractures of the spine in patients with AS and DISH are usually unstable fractures requiring surgical treatment. The aim of this study was to retrospectively evaluate patient characteristics, diagnostic procedures, and treatment strategies in patients with AS and DISH at our center.

**Methods**

**Ethics**

The study was approved by the local ethics board. We performed the study in accordance with the Declaration of Helsinki.

**Study Protocol**

Patients diagnosed with AS or DISH based on radiographs obtained between 2017 and 2021 were considered eligible for this study. Inclusion criteria were patients with AS or DISH and fractures of the spine who underwent surgical treatment at our institution. For all patients, fractures were classified in accordance with the AO classification. The time from trauma to diagnostics and surgical procedures, as well as patient characteristics and patient outcome, was analyzed. Clinical outcome was assessed with the American Spinal Injury Association (ASIA) Impairment Scale and the British Medical Research Council (BMRC) grading system.

**Radiographic Analysis**

Preoperative CT and MRI studies were analyzed regarding the time from trauma to imaging and fracture-related parameters (Figs. 1 and 2). On CT imaging, data on the fracture classification, fractured level, and prev-
tence of bone fragments were acquired. MRI studies were analyzed regarding fractures and ligament injuries as well as intraspinal and prevertebral hematoma (Fig. 2).

**Statistical Analysis**

Statistical analysis was performed using Prism version 8.4.1 (GraphPad Software). Descriptive statistics including mean, median, minimum, maximum, and standard deviation were calculated for patient- and fracture-related characteristics, including radiographic measurements.

**Results**

**Patient Characteristics**

Overall, 60 patients (14 female and 46 male) with 66 fractures of the cervical, thoracic, and lumbar spine were analyzed. The median ASA-PS (American Society of Anesthesiologists physical status) class was 3 (range 2–4). The leading symptom of all patients at presentation was pain, and 25.0% of patients exhibited fracture-related neurological deficits. The trauma mechanisms were mainly minor traumas such as falls from a standing or sitting position (78.3%) (Table 1). Hyperextension in trauma was documented in 20 patients and flexion in 10 patients, whereas in 30 patients a trauma mechanism remained unclear due to syncopal falls of an unclear course. Five patients (8.3%) showed blood concentrations of alcohol at the time of the trauma. Fractures classified by the AO classification were B3 in 84.8% and C1 in 15.2%. Accompanying injuries occurred in 48.3% of patients, mainly head wounds (Table 1). At admission, 33.3% and 30% of patients were on a regimen of antiplatelet agents and oral anticoagulation medications, respectively, and deranged international normalized ratio values and platelet counts were found in 18.3% of patients.

**Diagnostics**

CT imaging was performed within 24 hours after the initial trauma in 73.3% of patients (44 of 60). Twenty-four patients presented as a referral from a primary care hospital for further treatment. In 7 patients a delay of diagnostics of 14.3 ± 20.6 days (range 1–60 days) was due to patients initially reporting only minor pain and getting medical advice for other medical issues, an increase in pain severity, or, as in 1 patient, new neurological deficits. In 10 (41.7%) of the 24 referred patients, overall diagnostics in the primary care hospitals were delayed by 8.8 ± 5.6 days (range 4–17 days) and, therefore, not treated initially, and 2 patients (8.3%) showed progressive neurological deficits before diagnostics were performed and the patients were referred to our center. In 1 patient (4.2%), a thoracic fracture was diagnosed after admission due to another spinal fracture. On CT scans, fracture-related absolute spinal canal stenosis was diagnosed in 13 patients (Table 2). MRI was performed within 24 hours after admission (door to MRI) in 76.7% of patients (Fig. 3). In 9 of 66 (13.6%) of the fractures, MRI was not performed pro-

LOS = length of stay; pts = patients.

Values represent the number of patients (%) or mean ± SD unless indicated otherwise. Both cohorts show a similar distribution of risk factors including the ASA-PS class and AO classification of fractures.

* Defined as trauma from a standing or sitting position.

**Surgical Data**

The timing of surgery was dependent on the patient’s neurological status. Surgery was performed within 48 hours in all 15 patients with fracture-related neurological deficits except for 1 patient with ongoing symptoms for several days who was transferred from abroad. Overall, eratively due to progressive neurological deficits and immediate surgery, or contraindications for routine MRI such as automatic implantable cardiac defibrillators. On MRI, all patients showed a rupture of the spinal ossified ligaments, and spinal epidural hematoma was found in 11 patients (21.2%), with 8 of those (72.7%) presenting with neurological deficits (p < 0.001) (Table 2).
surgery was performed 8.8 ± 13.7 days (range 0–86 days) after the trauma and 5.6 ± 8.0 days (range 0–35 days) after admission to our institution for all 60 patients. One patient’s condition deteriorated preoperatively, but bedrest was limited due to patient noncompliance.

Intraoperative cardiopulmonary decompensation required cardiopulmonary resuscitation (CPR) in 3 patients. One patient who required CPR in an initial, interrupted surgery also required CPR because of cardiac arrest in the second surgery for completion of the percutaneous pedicle screw construct.

Regarding surgical treatment of fractures of the thoracic and lumbar spine, dorsal instrumentation covering three vertebrae above and three vertebrae below the fractured level was performed in order to address the fairly long lever of the rigid spine. In one case of a fracture of the upper thoracic spine, an additional vertebral body replacement was performed due to excessive injury (Table 3).

In cases of a fracture of the cervical spine, dorsal instrumentation is usually performed two levels above and below the fractured level. Additional ventral instrumentation by anterior cervical disectomy and fusion was performed in 5 patients. Anterior stabilization was a secondary procedure in 3 patients, providing additional stability in 2 patients (1 patient had a great intervertebral gap, and 1 had a dorsal screw explantation in revision), and performed for a prevertebral infection in 1 patient. Percutaneous instrumentation was performed in 75.0% of the patients with thoracic and lumbar fractures (Table 3).

Clinical Outcome

During hospitalization, 80.0% of patients developed complications. The 30-day mortality was 10.0%, including 2 patients (3.3%) who received best supportive care. The 30-day readmission rate was 10.0%, with 1 patient incurring another spinal fracture (1.7%) and 1 patient having wound infections (3.3%) (Table 4). The mean preoperative and postoperative overall intensive care unit stay was 5.5 ± 11.2 days (range 0–59 days).

Surgical complications occurred in 18.3% of patients. Surgical revision was necessary in 13.3% of patients, with screw revision due to construct failure in 2 patients. Wound healing disorders, including wound infections, were reported in 8.3% of patients.

Due to multiple comorbidities requiring treatment during hospitalization, 76.7% of patients developed further medical issues, with pneumonia (38.3%), pulmonary decompensation (25.0%), and cardiac decompensation (20.0%) being the leading causes (Table 4).

Regarding patient outcome, 5 patients improved in motor function postoperatively, whereas 2 patients deteriorated in motor function (Table 5). Four patients had improved ASIA grades postoperatively (Table 5). One patient showed trauma-related compression of both vertebral arteries and received best supportive care due to extensive cerebral ischemia.

Discussion

General Aspects

Fractures of ankylosing disease are complex, regarding patient characteristics, diagnostics, and surgical treatment. Patients with ASDs exhibit progressive kyphosis and an impaired muscle strength including the ability for com-
pensation, which results in a poorer body balance and, therefore, an increased risk of falls.\textsuperscript{5,6} Furthermore, ectopic bone formation and reduced bone quality result in a further increased risk of fractures;\textsuperscript{3,4} studies have shown an increased risk of fractures and an 11.4 times increased risk of spinal cord injury.\textsuperscript{7} Older age and multiple comorbidities often requiring intensive medical care during hospitalization result in an overall increased perioperative risk.

Regarding the trauma mechanism, a majority of patients had only minor traumas like falls from a standing or sitting position. Hyperextension was the most frequent cause of trauma in this study, which also correlates with previous findings.

### Diagnostic Pitfalls

On radiographic imaging, the increased vulnerability of the whole spine must be taken into consideration, with multilevel injuries occurring in 15.0% of patients in our study. Thus, diagnostics of the whole spine in patients with ASDs is required.\textsuperscript{5,9} In addition to CT scans, MRI is mandatory to further examine small fracture lines, prevertebral hematoma, nerve and spinal cord injury, and epidural hematoma. Until proven otherwise, patients with AS or DISH who fall should be considered to have sustained a spinal injury.\textsuperscript{10} Especially in patients who present with minor trauma and who are treated for syncopal events involving cardiopulmonary treatment, possible spinal injury must not be ignored. Additionally, prolonged time until diagnosis is a common issue among patients with AS.\textsuperscript{11,12} In our study, in 33% of patients from primary care centers, fractures were not correctly identified or only identified after a prolonged period of time. This correlates with findings from other trauma centers reporting rates of delayed diagnosis of up to 45%.\textsuperscript{13,14} A previous study on patients with AS found a delay in diagnosis in 17.1% of patients, with delay being related to both the treating physician and the patient seeking medical attention.\textsuperscript{15}

### Surgical and Medical Complications

Conservative fracture treatment is not recommended due the extensive mechanical instability resulting in a high risk of secondary spinal cord injury.\textsuperscript{16} For patients with a spinal cord injury, there is a significantly increased risk for complications and a prolonged hospital stay.\textsuperscript{17} Strict bedrest and en bloc mobilization are obligatory until surgical treatment.

Surgical treatment of fractures in patients diagnosed with ASDs is challenging. In general, surgery is limited by the multimorbidity of the patients and requires minimally invasive surgery with minimal blood loss and surgery duration.\textsuperscript{10,18,19} Ull et al. reported rates of chronic heart failure as high as 68.4% and a rate of chronic obstructive pulmonary disease of 30.5%.\textsuperscript{14} Intraoperative complications such as cardiac failure eventually leading to intraoperative reanimation must be considered.

Regarding anesthesia, a reduced mobility of the cervical spine often requires fiberoptic intubation or intubation by video laryngoscope.\textsuperscript{10,20} In addition to the challenging cardiac status of many of these patients, critical respiratory particularities of a rigid thorax and potentially preinjured lung due to trauma require experienced aneste-

Surgical Technique

In fractures of the thoracolumbar spine, posterior-only instrumentation of three levels above and below the fracture level with or without additional decompression, is recommended\(^8,16,18,23\) (Fig. 1). When it comes to fractures of the cervical spine, anterior instrumentation alone is not sufficient, but regarding dorsal or combined doroventral instrumentation, the evidence is not clear and decision-making on a case-by-case basis is required.\(^18,24\) Yet, in patients with critical status, immediate anterior cervical surgery in the supine position can be an option for an initial safe and quick decompression. This is also represented in our data. Final fixation, however, then requires secondary posterior instrumentation.

Instrumentation should be performed percutaneously, especially when considering the high number of patients on regimens of antiplatelet agents (33.3%) and oral anticoagulation.\(^18,25,26\) For improved stability of the construct, cement augmentation of the pedicle screws is recommended because of reduced bone quality. Yet, the rigid thorax, and therefore the problematic respiratory situation of these patients during pre- and postoperative care, needs to be taken into account because of the risks of cement embolism.

Timing of Surgery

Fractures in patients with AS show extensive mechanical instability resulting in a high risk of secondary spinal cord injury and, therefore, require urgent surgical treatment. In patients with neurological deficits, surgery should be performed without a time delay to prevent further neurological deterioration. However, patients with AS are at high risk due to multiple comorbidities, advanced age, and often-restricted cardiopulmonary capacity.\(^18\) Furthermore, a majority of patients were on a regimen of antiplatelet agents and oral anticoagulation medications, resulting in increased intraoperative bleeding with increased intraoperative transfusion, and substitution of hemostatic agents and postoperative hematoma in cases of immediate surgery. In addition to that, only one case of neurological deterioration preoperatively, partially caused by patient noncompliance, was observed. This outlines that strict bedrest and en bloc mobilization are sufficient in most cases until surgery can be performed in an optimized setting.

Conclusions

Patients with ASDs must be treated with special care. They are at high risk of spinal injury after minor trauma, which requires thorough imaging of the entire spine. Fractures result in extensive instability and require percutaneous long-segment dorsal instrumentation. Patients and families need to be aware of the high perioperative medical complication rate including increased mortality due to the considerable comorbidities typical of this population. Treatment centers need to be capable of managing all upcoming medical or surgical events.

Acknowledgments

This trial was funded entirely by institutional grants from the Department of Neurosurgery, Technical University of Munich, Germany, School of Medicine, Klinikum rechts der Isar.
