ABSTRACT
A computed line list for formaldehyde, $\text{H}_2^{12}\text{C}^{16}\text{O}$, applicable to temperatures up to $T = 1500$ K is presented. An empirical potential energy and $ab$ initio dipole moment surfaces are used as the input to nuclear motion program TROVE. The resulting line list, referred to as $\text{AYTY}$, contains 10.3 million rotational-vibrational states and around 10 billion transition frequencies. Each transition includes associated Einstein-A coefficients and absolute transition intensities, for wavenumbers below 10 000 cm$^{-1}$ and rotational excitations up to $J = 70$. Room-temperature spectra are compared with laboratory measurements and data currently available in the HITRAN database. These spectra show excellent agreement with experimental spectra and highlight the gaps and limitations of the HITRAN data. The full line list is available from the CDS database as well as at www.exomol.com.

1 INTRODUCTION
Formaldehyde, $\text{H}_2\text{CO}$, is a poisonous molecule in the aldehyde group. On Earth it plays a part in troposphere chemistry dynamics as the main source of OH via photo-dissociation and is formed from photo-oxidation in the atmosphere or through the incomplete burning of biomass (Wayne 2000). Traces of formaldehyde have tentatively been detected in the martian atmosphere (Korablev et al. 1993) where it is believed to be derived from the oxidation of methene (C$_2$H$_4$) (Villanueva et al. 2013).

Formaldehyde was the first polyatomic molecule to be detected in the interseller medium (ISM) (Zuckerman et al. 1970) and is extremely abundant (Langer 1976). This has made it useful in investigating the isotope composition of carbon in the galaxy (Zuckerman et al. 1974). The proposed mechanism of production is via the successive hydrogenation of CO (Woon 2002) on icy grain mantles:

$$\text{H} + \text{CO} \rightarrow \text{HCO}$$
$$\text{H} + \text{HCO} \rightarrow \text{H}_2\text{CO}. \quad (1)$$

Further hydrogenation produces methanol through an intermediate methyl radical $\text{H} + \text{H}_2\text{CO} \rightarrow \text{CH}_3\text{O} \rightarrow \text{H} + \text{CH}_2\text{O} \rightarrow \text{CH}_3\text{OH}$. Common reactions include that with ammonia which produces amines (Schutte 2002) and polymerisation with other H$_2$CO molecules. As a result, formaldehyde is believed to be the major precursor for the formation of complex organic molecules in the ISM that include interstellar glycolaldehyde (Hollis et al. 2001) and amino acids (Schutte 2002).

Formaldehyde’s astrophysical relevance does not end in the ISM. Recently, it has been detected in comets (Bockelee-Morvan & Crovisier 1992), such as 103P/Hartley 2 (Dello Russo et al. 2011), C/2007 N3 (Villanueva et al. 2011) and Hale-Bopp (Milam et al. 2006), where it is thought to originate from the degradation of polyoxymethylene (Cottin et al. 2001). It is also present in protoplanetary discs around low mass young stars (Taurus-Aurura Class I/II) (Oberg et al. 2010; Zasowski et al. 2009; Sargent et al. 2014) as circumstellar ice with an abundance ratio of $\approx 2\%$ compared to the more ubiquitous water-ice.

Because of H$_2$CO’s role as a precursor to complex organic molecules, it is considered a possible biomarker. The RNA world hypothesis suggests an early Earth with a CO$_2$, H$_2$O and N$_2$ rich atmosphere (Neveu et al. 2013). Illuminating this mix with ultraviolet (UV) radiation should lead to a large amount of formaldehyde being fixed in the atmosphere before being deposited into the prebiotic oceans (Neveu et al. 2013). Alternatively, the source of prebiotic chemical compounds may be derived without need of illuminating UV radiation via glancing icy body impacts (Goldman & Tamblyn 2013). Such impacts would produce shock-compression conditions that lead to formation of HCN molecules. These HCN molecules can be
hydrolyzed to form formaldehyde and from there produce amino acids. Thus a planet rich in formaldehyde may indicate one undergoing the stages of pre-life.

Finally, formaldehyde masers Forster et al. 1988; Pratap et al. 1992 are a reliable and proven tracer for high-density environments such as star-forming regions in galaxies due to its ubiquity and large number of long wavelength transitions Mangum et al. 2008. Currently, there are 19 extragalactic sources Mangum et al. 2008 of these masers including IRAS 18566 + 0408, which is notable for detection of the first H2CO maser flare Araya et al. 2007. Formaldehyde masers (and maser flares) have mostly been observed via the 110 → 111 and 211 − 212 K-doublet transitions at 6.1 cm and 2.2 cm respectively.

The wide-range of interactions in atmospheric, terrestrial, astrophysical and astrobiological phenomena makes formaldehyde a relevant molecule in the chemistry of exoplanets and their atmospheres. Therefore a complete, high-resolution, line list for H2CO should provide an important aid for characterisation and modelling of formaldehyde. These considerations led us to study formaldehyde as part of the ExoMol project Tennyson & Yurchenko 2012, which aims to produce comprehensive molecular line lists for studies of the atmospheres of exoplanets and cool stars.

High-resolution, room-temperature formaldehyde spectra have been well-studied in the laboratory Johns & McKellar 1975; Brown et al. 1979; Nakanaga et al. 1982; Nadler et al. 1984; Cline & Varghese 1984; Reuter et al. 1989; Poulin et al. 1996; Theûlo et al. 2003); the early work was reviewed by Clouthier & Ramsay 1983. Currently, the major source of publicly available spectroscopic data on H2CO is the HITRAN database Rothman et al. 2013, which has recently been updated to include long-wavelength data from the CDMS database Müller et al. 2003. The spectral regions covered in the database are 0 – 100 cm−1, 1600 – 1800 cm−1 Perrin et al. 2000 and the 2500 – 5100 cm−1 Perrin et al. 2000 at up to 10−29 cm/molecule sensitivity for T=296 K. However, this accounts for only 40 000 transitions extending up to J = 64 and covers only four of the six fundamental vibrational bands as well as the ground state rotational spectrum. This deficiency arises from an apparent lack of absolute intensities in the 100 – 1600 cm−1 range. Additional observed transitions are available Perrin et al. 2003 and include line positions Perrin et al. 2003; Trhana et al. 2007; Zhao et al. 2007, and intensities Perrin et al. 2003, 2006; Flaud et al. 2006 of some of the fundamental bands and hot bands Hto et al. 1994; Perez et al. 2006; Margules et al. 2009. The incompleteness and low rotational excitations available in HITRAN limits the applicability of this data for temperatures above 300 K. The theoretical spectra presented in this paper aims to provide a more complete and accurate picture of the spectra of formaldehyde up to 10 000 cm−1 and for temperatures up to 1500 K. Our line list should therefore be useful for modelling higher temperature environments as well as studies on non-LTE transitions such as those observed in masers.

Theoretically, electric dipole transition intensities of H2CO were studied by Luckhaus et al. 1996 and Carter et al. 2003; see also the review by Yurchenko 2014. Luckhaus et al. 1996 used an ab initio MP2/6-311G** DMS to simulate the photoacoustic spectrum of high C-H stretching overtones of H2CO. Carter et al. 2003 generated an ab initio couple-cluster CCSD(T)/aug-cc-pVTZ dipole moment surface (DMS) for H2CO; they used an effective charges representation to compute (relative) rovibrational line intensities for H2CO reproducing the HITRAN data Rothman et al. 2004 with reasonable agreement Poulin et al. 1996 computed an ab initio DMS using the QCISD/6-3111G(d,p) level of theory and presented it as an expansion.

Despite these works there is no comprehensive line list for formaldehyde available in the literature. The goal of this work is to bridge this gap. We use the variational program TROVE Yurchenko et al. 2007 in conjunction with an initial potential energy surface (PES) obtained ‘spectroscopically’ by Yachmenev et al. 2011 and a new ab initio dipole moment surface (DMS) for formaldehyde and generate an extensive line list for H216O applicable for the temperatures up to T = 1500 K. In the following H2CO and formaldehyde will refer to the main isotopologue H216O.

2 METHOD

2.1 Background

H2CO is a prolate asymmetric top molecule that belongs to the C2v molecular symmetry group Bunker & Jensen 1998. The group has four irreducible representations A1, A2, B1, and B2. Once the H atom nuclear spin is taken into account the ‘para’ A representations are singly degenerate and the ‘ortho’ B representations are triply degenerate. As H2CO has four atoms, it has six vibrational modes; Table 1 shows the vibrational modes and their corresponding symmetries, band centers and descriptions. Coriolis interactions occur strongly between the ν4 and ν6 modes, and weakly between the ν3 and ν4 modes Nakagawa & Morino 1971 which couples their energy levels and wavefunctions. This manifests itself in the ν3, ν4 and ν6 mode interaction as overlapping bands which make these three bands difficult to distinguish from each other.

2.2 Potential energy surface

Full details of their PES calculation are given by Yachmenev et al. 2011, so only a brief summary is presented here. The initial PES was computed ab initio using the CCSD(T)/aug-cc-pVQZ theory. Variational calculations with this surface give a
Table 1. Vibrational modes and observed band centres in cm$^{-1}$ by Carter et al. (1993).

| Mode | Band Centers | Symmetry | Description                  |
|------|--------------|----------|------------------------------|
| $\nu_1$ | 2782.46     | $A_1$    | symmetric C-H stretching     |
| $\nu_2$ | 1746.01     | $A_1$    | C-O stretching               |
| $\nu_3$ | 1500.18     | $A_1$    | symmetric O-C-H bending      |
| $\nu_4$ | 1167.26     | $B_1$    | out-of-plane bending         |
| $\nu_5$ | 2843.33     | $B_2$    | asymmetric C-H stretching    |
| $\nu_6$ | 1249.10     | $B_2$    | asymmetric O-C-H bending     |

Figure 1. Overview of the $\nu_3$, $\nu_4$ and $\nu_5$ region between different PES used in production and PNNL-IR Sharpe et al. (2004) cross-sections: (a) represents the over-refined PES (b) the ‘better’ refinement. Note the difference in y-axis scaling in (a) to highlight structural features.

2.3 Variational computation

The TROVE program suite Yurchenko et al. (2007) is employed to compute our formaldehyde line list as well to perform the least-squares fit of the ab initio PES discussed above. TROVE is designed to compute variational ro-vibrational energy levels, associated eigenfunctions and transition intensities for molecules of arbitrary structure. Variational methods are often limited in their efficiency due to the need to diagonalize increasingly large Hamiltonian matrices as the complexity of the molecule increases. However with the improved computational power and parallelism of modern CPUs, it is now feasible to solve ro-vibrational Schrödinger equations for polyatomic molecules. TROVE has been successfully used to produce high-accuracy line lists and spectra for tetratomic molecules such as HSOH Yurchenko et al. (2010), NH$_3$ Yurchenko et al. (2011), SO$_3$ Underwood et al. (2013), PH$_3$ Sousa-Silva et al. (2013, 2013), and SbH$_3$ Yurchenko et al. (2010), as well as recently the pentatomic molecule CH$_4$ Yurchenko & Tennyson (2014).

TROVE approximates the kinetic energy operator (KEO) by a truncated Taylor series expansion in generalized coordi-
nates. Previous calculations for H$_2$O$_2$ by Polyanovsky et al. (2013) show that computations using series representation of the KEO for non-linear molecules, such as H$_2$CO, converge as well as exact KEO-based programs such as WAVR4 (Kozin et al. 2004) and, particularly for excited rotational states, at cost of significantly less computational time. In this work we use a kinetic expansion order of 6 for optimal convergence while providing reasonable computation times and similarly, we use a potential energy expansion order of 8.

In TROVE, the primitive vibrational basis set is represented by a symmetrized product of six one-dimensional vibrational functions $\phi_{n_1}(r_1^i)$, $\phi_{n_2}(r_2^i)$, $\phi_{n_3}(r_3^i)$, $\phi_{n_4}(\theta_1^i)$, $\phi_{n_5}(\theta_2^i)$, and $\phi_{n_6}(\tau)$, where $n_i$ denotes the associated local mode vibrational quanta, $\{r_1^i, r_2^i, r_3^i, \theta_1^i, \theta_2^i, \tau\}$ are linearized versions of the coordinates $\{r_{CO}, r_{CH_2}, r_{CH_3}, \theta_{OCH_1}, \text{ and } \theta_{OCH_2}\}$, respectively, and $\tau$ is the dihedral angle between the OCH$_1$ and OCH$_2$ planes. The functions $\phi_{n_i}(q_i)$ are obtained by solving the corresponding 1D Schrödinger equation (Yurchenko et al. 2007) for the vibrational motion associated with the corresponding coordinate $q_i \in \{r_1^i, r_2^i, r_3^i, \theta_1^i, \theta_2^i, \tau\}$, with the other coordinates held fixed at their equilibrium values, where the Numerov-Cooley method (Numerov 1924, Cooley 1961) is used. The direct product of the 1D basis functions is contracted using the polyad condition:

$$P = 2(n_2 + n_3) + n_1 + n_4 + n_5 + n_6 \leq P_{\text{max}},$$

which in terms of the normal mode quantum numbers $v_i$ reads

$$P = 2(v_1 + v_5) + v_2 + v_3 + v_4 + v_6 \leq P_{\text{max}}.$$  

This polyad rule is based on the approximate relationship between the H$_2$CO fundamental frequencies (see Table 1):

$$v_1 \approx v_5 \approx 2v_2 \approx 2v_3 \approx 2v_4 \approx 2v_6.$$  

The vibrational basis set is further optimized by solving four reduced eigen-problems variationally for $\{q_1\}$, $\{q_2, q_3\}$, $\{q_4, q_5\}$, and $\{q_6\}$ to produce four sets of wavefunctions $\Phi^{(1)}_{n_1}(q_1)$, $\Phi^{(2,3)}_{n_2, n_3}(q_2, q_3)$, $\Phi^{(4,5)}_{n_4, n_5}(q_4, q_5)$, and $\Phi^{(6)}_{n_6}(q_6)$, respectively. At the step 2 the pure vibrational ($J = 0$) problem is solved variationally using the basis set constructed as a symmetrized direct product of $\Phi_i^{(i)}(i = 1, 6)$ and $\Phi_i^{(j, k)}(j, k = 2, 3$ or $4, 5)$ contracted through the polyad number condition (2) and symmetrized according to the C$_{2v}$ (M) molecular symmetry group. In this work the basis set is truncated at $P_{\text{max}} = 16$ as the relative simplicity of the molecule means that this gives well-converged results. The maximum polyad number $P_{\text{max}}$ restricts the number of combinations of $\phi_{n_1}^{(i)}$ and $\Phi_{n_1, n_2}^{(i, j)}$ for which $P \leq P_{\text{max}}$. The resulting eigenfunctions $\Psi_i^{J = 0, \Gamma}$ obtained for each C$_{2v}$(M) symmetry $\Gamma = A_1, A_2, B_1$ and $B_2$ together with the symmetrized rigid rotor wavefunctions $|J, K, \tau_{\text{rot}}\rangle$ form our $J = 0$ basis set representation (Yurchenko et al. 2009), where the ro-vibrational basis functions are given as a direct product of $\Psi_i^{J = 0, \Gamma}$ and $|J, K, \tau_{\text{rot}}\rangle$. Here $\tau_{\text{rot}}$ is the rotational parity defined by Yurchenko et al. (2005a), and $K$ is the projection of the angular momentum on the body-fixed axis $z$. The latter is defined according with the Eckart conditions (Eckart 1933) and is oriented approximately along the CO bond. In C$_{2v}$(M) symmetry, $K$ and $\tau_{\text{rot}}$ correlate with the customary $K_a$ and $K_c$ rotational quantum numbers as

$$K = K_a, \quad \tau_{\text{rot}} = \text{mod}([K_a - K_c], 2).$$

The vibrational part of the $J = 0$ basis set is truncated using the energy threshold of $\hbar c 18,000$ cm$^{-1}$ and thus consists of 2310, 1531, 1688, and 2112 functions for the $A_1, A_2, B_1$ and $B_2$ symmetries, respectively.

The resulting ro-vibrational Hamiltonian matrix in the $J = 0$ representation exhibits a block diagonal structure where each of four blocks represents an irreducible representation $A_1, A_2, B_1$ or $B_2$ and can be diagonalised independently. Each of these blocks displays a band-diagonal structure whose bandwidth and length is determined by the $J = 0$ basis set size and the level of rotational excitation respectively.

In generating our line list we employed an upper eigenvalue limit of 18 000 cm$^{-1}$ as the intensity of transitions involving higher energy states are too weak to be important. The $J = 0$ matrix blocks produced by TROVE were on average dimensions 1920 $\times$ 1920. The rule of thumb for the average size of a block for $J \geq 1$ is 1920($2J + 1$). The largest $J$ computed was $J = 70$ which required the diagonalisation of matrices in the order of $\approx 300,000$ for eigenvalues and eigenvectors. The linear algebra libraries LAPACK (Anderson et al. 1999) and SCALAPACK (Blackford et al. 1997) were employed to solve for the eigenvalues and eigenvectors.

### 2.4 Dipole moment surface and intensities

Intensity computation requires high quality electric DMS. We use an $ab\ initio$ DMS computed at the CCSD(T)/aug-cc-pVQZ level of theory in the frozen-core approximation using CFOUR (Harding et al. 2008). Three symmetry-adapted projections of the dipole moment Cartesian components, $\mu_{A_1}, \mu_{B_1},$ and $\mu_{B_2}$, are given in the analytical representations with each component expanded in Taylor series (185 parameters in total) in terms of internal coordinates around the equilibrium configuration using the form developed by Yachmenev et al. (2013) to represent the dipole moment of H$_2$CS. These parameters reproduce the $ab\ initio$ dipole moment values of the $\mu_{A_1}, \mu_{B_1},$ and $\mu_{B_2}$ components with rms errors of 0.0002 Debyes for each component. The equilibrium value of our dipole moment is 2.3778 D (at $r_{CO} = 1.2033742$ Å, $r_{CH} = 1.10377$ Å, $\theta_{OCH} = 121.84^\circ$), which
can be compared to the experimental value of the ground vibrational state dipole moment of $\mu=2.3321(5)$ D measured by Fabricant et al. (1977).

The eigenvectors, obtained by diagonalization, are used in conjunction with the DMS to compute the required linelists (and from that the Einstein-A coefficients and absolute intensities) of transitions that satisfy the rotational selection rules

$$J' - J'' = 0, \pm 1, J' + J'' \neq 0$$

and the symmetry selection rules

$$A_1 \leftrightarrow A_2, B_1 \leftrightarrow B_2.$$  

The Einstein-A coefficient for a particular transition from the initial state $i$ to the final state $f$ is given by:

$$A_{if} = \frac{8\pi^4 \overline{\nu}_f^3}{3h} (2J_i + 1) \sum_{X,Y,Z} |\langle \Psi_f | \mu_A | \Psi_i \rangle|^2,$$

where $J_i$ is the rotational quantum number for the initial state, $h$ is Planck’s constant, $\overline{\nu}_f$ is the transition frequency ($h\overline{\nu}_f = E_f - E_i$), $\Psi_f$ and $\Psi_i$ represent the eigenfunctions of the final and initial states respectively, $\mu_A$ is the electronically averaged component of the dipole moment along the space-fixed axis $A = X,Y,Z$ (see also Yurchenko et al. (2005b)). From this the absolute absorption intensity is determined by:

$$I(f \leftrightarrow i) = \frac{A_{if}}{8\pi c g_i} g_{ns}(2J_f + 1) \exp\left(-\frac{E_i}{Q \overline{\nu}_f} \right) \left[1 - \exp\left(-\frac{\hbar \overline{\nu}_f}{kT} \right) \right],$$

where $k$ is the Boltzmann constant, $T$ the absolute temperature and $g_{ns}$ is the nuclear spin statistical weight factor. $Q$, the partition function, is given by:

$$Q = \sum_i g_i \exp\left(-\frac{E_i}{kT} \right),$$

where $g_i$ is the degeneracy of a particular state $i$ with energy $E_i$. For H$_2$CO, $g_i$ is $g_{ns}(2J_i + 1)$ with $g_{ns} = 1$ for $A_1$ and $A_2$ symmetries and $g_{ns} = 3$ for $B_1$ and $B_2$ symmetries. The transitions were computed using the energy limits $\hbar c 8000$ and $\hbar c 18\ 000$ cm$^{-1}$ for the lower and upper states, respectively.

Although diagonalisation of the Hamiltonian matrices is very demanding on computer resources, it is the calculation of the Einstein-A coefficients which dominates the actual computer time due the sheer number of these and the large size of the eigenvectors. Graphics processing units (GPU) were therefore employed to accelerate computation of the intensities. To do this required the development of a new algorithm to allow these fast but memory poor processors to be used efficiently. A paper discussing this will be published elsewhere (Al-Refaie et al. 2015).

3 RESULTS

The line list produced, which we call AYTY, contains around 10 billion transitions with wavenumbers up to 10 000 cm$^{-1}$. The transitions are sorted in increasing transition frequency and then converted into the ExoMol format (Tennyson et al. 2013). An extract of the state file and transition file can be seen in Tables 2 and 3. Spectra at arbitrary temperatures can be computed using the Einstein-A coefficients from the transition files. The theoretical error as estimated by the fitting rms deviation of 0.18 cm$^{-1}$. This means our transition frequencies and energy levels should be reliable to about 0.2 cm$^{-1}$ with low-lying levels, particularly the pure rotational ones, being much more accurate than this and levels for vibrational states for which there are no available laboratory data much less so.

The completeness of the line list as a function of temperature can be determined by checking the convergence of the temperature-dependent partition function $Q$ given in Eq. (10), which is computed via explicit summation (Vidler & Tennyson 2000) of the 10.3 million energy levels available. As $T$ increases, a greater proportion of these states are required as their contribution towards $Q$ becomes more important. Figure 4 shows our computed partition function as a function of the maximum $J$ value ($J_{\text{max}}$) used in the calculation. As $J_{\text{max}}$ increases, each $J$ contributes progressively less until convergence is reached. The partition function at $T = 296$ K converges to better than 1% at $J \approx 34$ with the limit of $Q = 2844.621$ at $J = 58$. For $T = 1500$ K, it converges to about 0.005% at $J = 70$ with a $Q$ value of 130 190.25. These partition functions can be used to evaluate the effect of lower energy state threshold of 8000 cm$^{-1}$ on the completeness of the line list by comparing $Q_{\text{limit}}$, which sums energies up to this threshold, with the full partition sum. Figure 5 shows that the two partition functions are essentially the same up to 800 K and that $Q_{\text{limit}}$ is 92.3 % of $Q$ at $T = 1500$ K. Therefore we recommend $T=1500$ K as a ‘soft’ limit to the applicability of the line list. Use of the line list at higher temperatures will lead to the progressive loss of opacity although the ratio $Q_{\text{limit}}/Q$ can be used to estimate the proportion of this missing contribution (Neale et al. 1998).

Table 5 compares our partition functions with those from CDMS (Müller et al. 2003) and those used in HITRAN (Fischer et al. 2003). At temperatures $T \leq 300$ K we agree to better than 1% with CDMS and HITRAN. At 500 K the difference with CDMS is much higher at 8.9%, due our explicit sum running over a much larger number levels, but agreement
Table 2. Extract from the H$_2$CO state file. The full table is available at [http://cdsarc.u-strasbg.fr/cgi-bin/VizieR?-source=J/MNRAS/](http://cdsarc.u-strasbg.fr/cgi-bin/VizieR?-source=J/MNRAS/).

| 6709468 | 6722660 | 3.2621e-05 |
| 6704996 | 6726710 | 4.7333e-05 |
| 6726711 | 6739070 | 5.0697e-05 |
| 6718218 | 6730865 | 5.4273e-05 |
| 6730866 | 6750469 | 5.6752e-05 |

$f$: Upper state counting number; $i$: Lower state counting number; $A_{fi}$: Einstein-A coefficient in s$^{-1}$.

The expansion parameters given in Table 4 reproduce our partition function better than 0.3% for temperatures ranging up to 3000 K.

The dependance of the cross-sections on temperature is illustrated in Figure 4, the features in the simulated spectra become smoother as the temperature increases. This is a result of the vibrationally excited states becoming more populated and the increasing width of the rotational envelope with temperature. Figure 5 shows a simulated $T = 296$ K spectrum computed from our line list against the available laboratory absorption spectra up to 10 000 cm$^{-1}$. The logarithmic scale used with HITRAN is good. There are bigger differences at higher temperatures: at 1500 K our partition function is lower by about 1.2% and at 3000 K by 9.7%. This may be caused by the lack of the high energy contributions due to the energy cut-off of $hc18000$ cm$^{-1}$ used in our line list, see Sousa-Silva et al. (2014) and Neale & Tennyson (1995) for a discussion of the importance of contributions from the excited ro-vibrational states up to the dissociation. Our full partition function evaluated on a 1 K grid is given in the supplementary data. We use the analytical representation suggested by Vidler & Tennyson (2000) as given by

$$ \log_{10} Q(T) = \sum_{n=0}^{8} a_n [\log_{10} T]^n. $$

The expansion parameters given in Table 4 reproduce our partition function better than 0.3% for temperatures ranging up to 3000 K.
Figure 2. Partition functions at two temperatures as a function of inclusion of rotational states: all \( J \) up to \( J_{\text{max}} \) for \( T = 296 \) K (left hand scale) and \( T = 1500 \) K (right hand scale).

Table 4. Parameters used to represent the partition function, see Eq. (11), valid for temperatures up to 3000 K.

| Parameter | Value         |
|-----------|---------------|
| \( a_0 \) | 1.12789807683 |
| \( a_1 \) | -5.35067939866 |
| \( a_2 \) | 10.33684323700 |
| \( a_3 \) | -4.92187455147 |
| \( a_4 \) | -2.28234089365 |
| \( a_5 \) | 3.61122821799  |
| \( a_6 \) | -1.64174365325 |
| \( a_7 \) | 0.33727543206  |
| \( a_8 \) | -0.02654223136 |

shows the density of transitions in our line list and reveals the significant gaps and limitations in the HITRAN 2012 database. Comparing specific regions, our line list accurately replicates both the line positions and intensities of the three available bands, as illustrated in detail in Fig. 6. Additional lines are present as our computed spectra contains all possible transitions within the region including hot bands. Fig. 6 and Table 7 show agreement with the line positions and absolute intensities from Reuter et al. (1989) with an rms deviation of 0.099 cm\(^{-1}\) for the line positions. There are some limitations with our line list. Higher \( J \) transitions at around the \( J > 50 \) range begin to show a slight drift of \( \approx 0.3 \) cm\(^{-1}\) in predicted line position; this does not occur for the rotational band. In practice, errors in the ro-vibrational energy levels grow with \( K \) (as opposed to \( J \)); the discrepancies in transition frequencies become more pronounced in \( |K' - K''| = 1 \) transitions than those that involve the same \( K \) (\( K' = K'' \)). This can be seen in the lack of drift in the pure rotational band as it is mostly comprised of \( K' = K'' \) transitions due to both ground and excited states being of \( A_1 \) symmetry. \( B_1 \) and \( B_2 \) vibrational bands however are mostly comprised of \( |K' - K''| = 1 \) transitions which makes their errors more sensitive to the quality of the model.

Computing band intensities requires simulating spectra at a chosen temperature and accumulating all transitions that correspond to the specific band. Table 6 highlights our band intensities against those available in the literature. Each band intensity required spectra simulated to the parameters used by each reference. In general, AYTY agrees well with all band intensities but is more intense. This may be due to the fact that AYTY sums over all lines in a given band whereas experiments generally only capture the strongest lines. Table 6 also shows the total band intensity for the 3.5 \( \mu \)m region compared to that by Brown et al. (1979), Nakanaga et al. (1982) and HITRAN. Our value is 13 % stronger than HITRAN, (matches the discrepancy for the \( \nu_1 \) and \( \nu_5 \) bands in Table 7), 18 % stronger than Nakanaga et al. (1982) and 40 % stronger than that by Brown et al. (1979). Absolute intensities and bands not available in the HITRAN database or literature can be evaluated against cross-sections. For the \( \nu_3 \), \( \nu_4 \) and \( \nu_6 \) bands, further evaluation of these bands can be made against cross-
Figure 3. Plot of $Q_{\text{limit}}/Q$ against temperature where $Q_{\text{limit}}$ is the partition function computed using only energy levels below our lower state threshold of 8000 cm$^{-1}$.

Table 5. Comparisons of H$_2$CO partition functions as a function of temperature for this work, CDMS (Müller et al. 2005) and those used in HITRAN (Fischer et al. 2003).

| $T$ / K | AYTY  | CDMS  | HITRAN |
|--------|-------|-------|--------|
| 2.725  | 2.0163| 2.0166|        |

| 9.375  | 13.801| 13.8008|     |
| 18.75  | 44.6835| 44.6812|     |
| 37.5   | 128.6581| 128.6492|     |
| 75     | 361.7053| 361.7195| 362.07|
| 150    | 1019.9549| 1019.9706| 1020.47|
| 225    | 1874.4679| 1872.6221| 1875.67|
| 300    | 2904.1778| 2883.0163| 2906.32|
| 500    | 6760.2315| 6208.3442| 6760.99|
| 1500   | 128635.40| 130190.25| 1500.00|
| 3000   | 2741283.3| 3038800.0|       |

sections available from the PNNL-IR database (Sharpe et al. 2004) and Nakanaga et al. (1982) using a Gaussian profile with a HWHM (half-width-half-maximum) of 1.1849 cm$^{-1}$ and 0.1120 cm$^{-1}$, determined from their respective experimental profiles. Figure 7a compares the AYTY line list with a spectrum extracted from Fig. 3 of Nakanaga et al. (1982) and scaled to match the AYTY line list. Good agreement is seen in both structure and position in the band with a slight drift occurring as an artifact from the extraction process. Figure 7b shows an even better agreement with the spectral structure as well as the cross-section intensity.

The total integrated cross-section over the region 6.2 – 10.5 µm for AYTY and PNNL is 8.02 × 10$^{-17}$ cm/molecule and 8.20 × 10$^{-17}$ cm/molecule respectively, making PNNL overall around 8% stronger. PNNL covers regions beyond those currently available in HITRAN. Figure 8(a) depicts the $2\nu_2$ band at 2.88 µm. Good agreement is seen in structure, position and cross-sections with the integrated cross-sections differing by only 10%. The regions below 2.8 µm in PNNL become increasingly polluted with noise but band features are still visible as seen in Figures 8(b),(c) and (d). In particular, Figure 8(b), the AYTY cross-section reproduces peaks in features present in the PNNL-IR data. This region was also studied by Flaud et al. (2006). Their absorbance spectrum produces certain transitions with double the intensity compared to AYTY.
Figure 4. Cross-sections of the entire AYTY line list as a function of temperature: The curves in the 16 \(\mu\)m region increase in opacity with increasing temperature.

Figure 5. Overview of our synthetic spectrum at \(T = 296\) K against HITRAN [Rothman et al. 2013], Reuter et al. [1989] and Zhao et al. [2007].
Figure 6. The fundamental bands compared to currently available experimental intensities (Rothman et al. 2013; Reuter et al. 1989; Müller et al. 2005) at \(T = 296\) K. (a) Rotational Band (b) \(\nu_2\) (c) \(\nu_1\) and \(\nu_5\) (d) \(\nu_3\), \(\nu_4\) and \(\nu_6\).

Figure 7. Cross-section comparison of AYTY against experimental of the \(\nu_3\), \(\nu_4\) and \(\nu_6\) band regions: (a) Nakanaga et al. (1982) at 296 K with HWHM = 1.1849 cm\(^{-1}\); Extracted from image and scaled to match the AYTY cross-section; (b) PNNL-IR data at 323.15 K (Sharpe et al. 2004) with HWHM = 0.1120 cm\(^{-1}\).
These are due to splitting caused by two transitions with the same quanta but with swapped $\Gamma_f$ and $\Gamma_i$ giving the two lines very similar transition frequencies and absolute intensity which make them difficult to resolve experimentally.

Further bands include the integrated cross-section for the $2\nu_5$ band at 5676.21 cm$^{-1}$ for AYTY and Barry et al. (2002) at $6.4 \times 10^{-22}$ cm$^2$/molecule and $5.6 \times 10^{-22}$ cm$^2$/molecule respectively making AYTY 11% stronger. In Table 6 we also compare theoretical (AYTY) overtone band intensities obtained by the direct summation with the corresponding experimentally derived values from Perrin et al. (2006); Flaud et al. (2006). The agreement with the data obtained by Flaud et al. (2006) is very good. Those from Perrin et al. (2006) are in fact a compilation of different sources (Hisatsune & Eggers 1955; Brown et al. 1979; Nakanaga et al. 1982; Herndon et al. 2005; Cline & Varghese 1988), some of which were obtained at low resolution, which could explain the slightly worse agreement with our calculations. Compare the total integrated band intensity for the band at 1.5 $\mu$m we obtain $3.11 \times 10^{-17}$ cm$^2$/molecule against 2.19, 2.62, and $2.73 \times 10^{-17}$ cm$^2$/molecule by Perrin et al. (2006), Nakanaga et al. (1982) and from HITRAN, respectively.

Finally, Ito et al. (1994) presented the relative band intensities as the ratio of the vibrational transition moments between $2\nu_4$ and $2\nu_6$ of 0.755(48), which can be compared to our absolute value of 0.6264.

4 CONCLUSION

We have computed the frequency and Einstein-A coefficients of almost 10 billion transitions of formaldehyde, which cover wavelengths longer that 1 $\mu$m and includes all rotational excitations up to $J = 70$, making the line list applicable for temperatures up to 1500 K. The AYTY line list gives a room-temperature spectrum in excellent agreement with available experimental data. We have highlighted those regions missing from the HITRAN database with the hope that they will be investigated further experimentally. The new line list may be accessed via www.exomol.com or http://cdsarc.u-strasbg.fr/viz-bin/qcat?J/MNRAS/.

The cross-sections of $H_2CO$ can be also generated at www.exomol.com as described by Hill et al. (2013).

5 ACKNOWLEDGEMENTS

This work was supported by the ERC under the Advanced Investigator Project 267219 and made use of the DiRAC@Darwin, DiRAC@COSMOS HPC cluster and Emerald CfI cluster. DiRAC is the UK HPC facility for particle physics, astrophysics and cosmology and is supported by STFC and BIS. The authors would like to acknowledge the work presented here made use of the EMERALD High Performance Computing facility provided via the Centre for Innovation (CfI). The CfI is formed from the universities of Bristol, Oxford, Southampton and UCL in partnership with STFC Rutherford Appleton Laboratory.
