We discuss classification of defects of various codimensions within a holographic model of pure Yang-Mills theories or gauge theories with fundamental matter. We focus on their role below and above the phase transition point as well as their weights in the partition function. The general result is that objects which are stable and heavy in one phase are becoming very light (tensionless) in the other phase. We argue that the θ dependence of the partition function drastically changes at the phase transition point, and therefore it correlates with stability properties of configurations. Some possible applications for study the QCD vacuum properties above and below phase transition are also discussed.

PACS numbers:

I. INTRODUCTION

The gauge/string duality proved to be effective in description of various aspects of gauge theories at weak and strong coupling. In the N=4 SYM one can discuss a precise comparison of the gauge theory results with the sigma model or SUGRA calculation since the relevant geometry \( AdS_5 \times S^5 \) is well established. However the situation in the theory with less amount of SUSY is much more complicated and the explicit background for the pure YM or QCD is not found yet. The most useful dual model of pure YM at nonzero temperature \([1]\) is based on a stack of \( N_c \) D4 branes which are wrapped around a compact coordinate and at large \( N_c \) provide the geometry of the black hole in \( AdS_5 \). Adding the probe \( N_f \) D8 – \( \bar{D} \)8 branes one
obtains the dual picture for QCD which reproduces the chiral Lagrangian and captures many qualitative aspects of the strong coupling physics.

In this Letter we shall discuss extended objects in QCD from the dual perspective. In the dual model the natural objects to consider are probe D-branes. The Sakai-Sugimoto model is based on the IIA side of the string theory hence there are stable D0,D2,D4,D6,D8 D branes as well as NS5 brane which we shall discuss on. We shall try to get qualitative picture concerning the role of the various defects which is insensitive to the details of the metric. The background involves two periodic coordinates, angular coordinate on the black hole cigar $x_4$ and the Euclidean time coordinate $\tau$ which branes can wrap around.

In the previous studies some identifications of the defects have been made. The D0 brane extended along $x_4$ was identified as the YM instanton. The D2 brane wrapped around both periodic coordinates was identified as the magnetic string. The D6 brane wrapped around the compact $S^4$ part of the dual geometry and $\tau$ was considered in pure YM and dual QCD where it has interpretation of the domain wall separating two vacua. The D4 brane wrapped around the $S^4$ and extended along $\tau$ has the interpretation of the "baryonic vertex" in pure YM and in the Sakai-Sugimoto model. Some interplay between the D branes and the $Z_N$ domain walls has been discussed in the holographic picture.

There are a few generic facts concerning the branes and their intersections. Let us numerate few of them relevant for the main text:

- p-brane behaves as an instanton on the (p+4)-brane worldvolume
- p-brane parallel to the (p+2)-brane gets melted into homogenous field
- p-brane transverse to the p+2-brane behaves as the monopole on the (p+2) worldvolume
- branes in external fields can expand into higher dimensional branes via the Myers effect

Our goal here is to look at a variety of defects using a universal classification scheme. We will be mostly interested in behavior of the corresponding configurations when the confinement-deconfinement phase transition is crossed and shall emphasize some universal properties of the D-defects. It is very likely that some of the defects to be discussed here are very important for physics, some of them could be irrelevant. Therefore, we anticipate
that some important/interesting defects will be further discussed and studied in great detail in future. It is not the goal of the present paper to go into a deep detail analysis of each particular configuration. Instead, our goal is the classification of the D-defects, with emphasis on the change of their properties across the phase transition.

To be more specific, our basic tool is the dual description of the deconfinement phase transition as the Hawking-Page phase transition \[1\], in which case the two metrics with the same asymptotic get interchanged. The wrapping around \(x_4\) is stable above the phase transition \(T > T_c\) while it is unstable below the critical temperature \(T < T_c\), see definitions and details below. And vice-verse, the wrapping around \(\tau\) is stable at small temperatures \(T < T_c\) and unstable at high temperatures, \(T > T_c\).

Since the nonperturbative physics is sensitive to the \(\theta\)-term we shall also discuss the \(\theta\) dependence from the dual perspective. We argue that the behavior of the D defects is strongly correlated with the \(\theta\)-dependence when the phase transition is crossed at \(T_c\). Such a drastic change in \(\theta\) dependence at the \(T_c\) has already been noticed in the literature \[3, 4, 15, 16, 17\]. We note also that some drastic changes in \(\theta\) behavior are also supported by the numerical lattice results \[18 - 22\], see also a review article \[23\], which unambiguously suggest that the topological fluctuations (related to \(\theta\) behavior) are strongly suppressed in deconfined phase, and this suppression becomes more severe with increasing \(N_c\). Here we shall present some additional examples which support this picture.

The paper is organized as follows. In Section II we describe our model based on the \(N_c\) D4 branes with one compact worldvolume coordinate. In our main Section III we classify D-defects treated in the probe approximation when they do not deform the dual geometry. In Section IV with discuss some composite objects which combine different types of D branes. Finally, in Section V we introduce matter fields in our system which treated as the probes, \(N_f \ll N_c\). Section VI is our conclusion.

II. DESCRIPTION OF THE MODEL

A natural starting point to discuss the dual holographic geometry is provided by a set of \(N_c\) D4 branes wrapped around a compact dimension \[1\]. We shall consider the pure gauge sector first and then add flavor D8 branes along the lines of the Sakai-Sugimoto model \[2\].

We shall assume the large \(N_c\) limit and consider the supergravity approximation. In this
approximation the geometry looks as $M_{10} = R_{3,1} \times D \times S^4$ and the corresponding metric reads as

$$ds^2 = \left(\frac{u}{R_0}\right)^{3/2}(-dt^2 + \delta_{ij}dx^idx^j + f(u)dx_4^2) + \left(\frac{u}{R_0}\right)^{-3/2}\left(\frac{du^2}{f(u)} + u^2d\Omega_4^2\right)$$

$$e^\Phi = \left(\frac{u}{R_0}\right)^4, \quad F_4 = \frac{3N_c \epsilon_4}{4\pi}, \quad f(u) = 1 - \left(\frac{u_A}{u}\right)^3 \quad (1)$$

where $R_0 = (\pi g_s N_c)^{1/3}$ and $R = \frac{4\pi}{3}(\frac{R^3}{u_A})^{1/2}$. The coupling constant of Yang-Mills theory is related to the radius of the compact dimension $R$ as follows

$$g_{YM}^2 = \frac{8\pi^2 g_s l_s}{R}$$

At zero temperature theory is in the confinement phase and in the $(u, x_4)$ coordinates we have the geometry of a cigar with the tip at $u = u_A$. The D4 branes are located along our (3+1) geometry and are extended along the internal $x_4$ coordinate. The key point is that in the non-zero temperature case there are two backgrounds with similar asymptotic topology of $R^3 \times S^1 \times S^1 \times S^4$, where $\tau$ is the Wick-rotated time coordinate $\tau = it$, $\tau \propto \tau + \beta$. One background corresponds to the analytic continuation of the metric described above while the second background corresponds to interchange of $\tau$ and $x_4$, that is the warped factor is attached to the $\tau$ coordinate and the cigar geometry emerges in the $(\tau, u)$ plane instead of $(x_4, u)$ plane which now exhibits the cylinder geometry, see Figure 1. It was shown in [1] by calculation of the free energies that above $T_c$ the latter background dominates.

That is above phase transition wrapping around the internal $x_4$ circle is topologically stable, while the wrapping around the Euclidean time coordinate is unstable. This is opposite to the stability pattern of the two wrappings below the phase transition.
Another issue which we shall be interested in concerns the $\theta$-dependence of the worldvolume theories on the different probe branes. It can be traced from the Chern-Simons (CS) terms involving the interaction with the RR one-form $C_1$

$$\delta L = \int C_1 \wedge e^F$$  \hspace{1cm} (2)

where $F$ is the gauge two-form. Taking into account that

$$\theta = \int dx_4 C_1$$  \hspace{1cm} (3)

one immediately recognizes that the $\theta$ dependence of the worldvolume theories on the defects correlates with the wrapping around $x_4$ coordinate. Moreover it is clear that the $\theta$ dependence of a single defect is poorly defined in the confined phase since the wrapping around $x_4$ is topologically unstable and one could discuss the $\theta$ dependence of a kind of a condensate of the defects.

To model QCD one adds the $N_f D8 - \bar{D}8$ pairs localized at points in $x_4$ coordinate. There are a few qualitative phenomena to be mentioned. First, the chiral symmetry breaking is described geometrically in terms of the connectness of the $D8 - \bar{D}8$ pair. It was argued that the restoration of the chiral symmetry and the deconfinement phase transition generically take place at different temperatures [24]. Another essential point concerns the baryonic degrees of freedom. Geometrically baryons are identified as the D4 branes wrapped around the compact $S^4$ and they are the instantons in the D8 brane worldvolume theory. Note that in the holographic QCD there should be some care concerning the gauge invariance of the RR field. The gauge invariant field strength of the RR field due to the bulk anomaly gets shifted by the $\eta'$ meson and the correct invariant identification of the $\theta$-term reads as

$$\int_D F_{2, inv} = \theta + \frac{\sqrt{2N_f}}{f_\pi} \eta'$$  \hspace{1cm} (4)

where the integration over the $u, x_4$ disc is implied.

In the thermal gauge theory a natural order parameter is the vacuum expectation value of the Polyakov loop

$$< W(\beta) > = < Tr P exp(\int d\tau A_0) >$$  \hspace{1cm} (5)

which is vanishing at $T < T_c$ while $< W(\beta) > \neq 0$ at $T > T_c$. This implies that $Z_N$ symmetry is unbroken at $T < T_c$ and broken at $T > T_c$. It is possible to discuss another R-type symmetry of the rotation of $x_4$ coordinate which is assumed to be broken nonperturbatively
at zero temperature to the discrete one similar to SUSY case. Therefore one could expect the total discrete symmetry to be $Z_N \times Z_N$ where the order parameter for the second factor is

$$< W(R) >= < Tr P e^{\int dx A_4} >$$

(6)

It can serve as the order parameter analogous to the Polyakov loop since it has a nontrivial vev at small temperatures and vanishes in the deconfinement phase. Let us emphasize that the total discrete group mentioned above differs from the same product discussed in [8]. In that paper the second factor corresponds to the S-dual magnetic center group whose order parameter is identified with the T’Hooft loop.

III. ZOO OF THE D- DEFECTS

A. D0 branes

**D0 instantons.**

The simplest defects to be discussed are D0 branes. It was argued in [3] that instantons are represented by the Euclidean D0 branes wrapped around $x_4$. In that case it was argued that the instanton is well defined above $T_c$ as it corresponds to the the geometry of the cylinder. On the other hand, any finite number of instantons are ill-defined below $T_c$ because of the D0-brane instability.

The $\theta$ dependence of the D0 action is captured by the CS term on its worldline. The change of the instanton role at the transition point corresponds to the change from the Witten-Veneziano to t’Hooft mechanisms of the solution to the $U(1)$ problem. In QCD-like brane setup D0 branes wrapped around $x_4$ intersect with the flavor branes and induce the sources on the flavor brane worldvolumes.

This picture can also be readily understood in the quantum-field theory terms since an estimation for $T_c$ in the $\Lambda_{QCD}$ units can be given [16]. Indeed, the wrapping around $x_4$ corresponds to the well defined small instanton and one can use the standard instanton calculus to estimate the critical temperature $T_c$ and the $\theta$ behavior above $T_c$:

$$V_{\text{inst}}(\theta) \sim \cos \theta \cdot e^{-\alpha N \left(\frac{T - T_c}{T_c}\right)}, \quad 1 \gg \left(\frac{T - T_c}{T_c}\right) \gg 1/N,$$

$$\chi(T) \sim \frac{\partial^2 V_{\text{inst}}(\theta)}{\partial \theta^2} \sim e^{-\alpha N \left(\frac{T - T_c}{T_c}\right)} \to 0, \quad \alpha \sim 1, \quad N \gg 1.$$

(7)
Such a behavior implies that the dilute gas approximation at large $N_c$ is justified even in close vicinity of $T_c$ as long as $\frac{T-T_c}{T_c} \gg \frac{1}{N_c}$. Such a sharp behavior of the topological susceptibility $\chi(T)$ is supported by numerical lattice results [18]-[22] which unambiguously suggest that the topological fluctuations are strongly suppressed in the deconfined phase, and this suppression becomes more severe with increasing $N_c$. These general features observed in the lattice simulations have very simple explanation within QFT framework as eq. (7) shows, as well as in holographic model of QCD [3, 16].

Finally, let us address the following question: what happens with our D0 instantons in the deconfined phase, immediately at $T > T_c$? We know that at sufficiently large temperatures $(T - T_c)/T_c \gg 1/N$ the configuration becomes a stable instanton in 4d with the size $\rho \sim (\pi T)^{-1}$. The density of the instantons is exponentially suppressed $\sim \cos \theta \cdot e^{-a N(T_c - T_c)/T_c}$, magnetic charges of the constituents (if exist, see section IV) are completely screened such that it makes no sense to speak about individual constituents in this regime. However, for finite $N$ there is a window of temperatures $0 < (T - T_c)/T_c \leq 1/N$ when the magnetic degrees of freedom are not completely screened yet. This window which shrinks to a point at $N = \infty$ is obviously beyond analytical control. However, these magnetic degrees of freedom could be extremely important in the window $0 < (T - T_c)/T_c \leq 1/N$. It is tempting to assume that these magnetic degrees of freedom is a trace of fractional instanton constituents which likely to exist in confined phase, see discussions in section IV.

**D0 - particle**

The orientation of the D0 brane worldline along the Euclidean time $\tau$ corresponds to its realization as a KK particle without the $\theta$ dependence. However the Polyakov loop $Tr P \exp(\int d\tau A(\tau))$ may develop. This configuration at $T < T_c$ is a stable scalar glue-like configuration which must have very different properties in comparison with all standard glueballs when the temperature approaches $T_c$ from below, $(T_c - T) \rightarrow 0$. Above the critical temperature (deconfinement phase) KK modes tend to condense near the tip of the cigar because of the instability of the wrapping around $\tau$. In the deconfinement phase KK modes behave as the instanton -like configuration (with no $\theta$ dependence) in the effective 3D gauge theory. This instability may have enormous consequences for physics since an arbitrary large number of such states can be produced in vicinity of $T \simeq T_c$. We shall not elaborate on this issue in the present work.
B. D2 branes

D2 string.  
The magnetic string is the probe D2 brane wrapped around $S_1$ parameterized by $x_4$ and its tension is therefore proportional to the effective radius $R(u)$ [4]. At small temperatures this wrapping is topologically unstable and the D2 brane tends to shrink to the tip where its tension vanishes. This is the large-$N_c$ counterpart of the effect of dissolving of $p$-branes inside $p + 2$-branes [12]. We see that in this way one immediately reproduces the observed property of tensionlessness of the magnetic string in the confining phase which however becomes tensionful above the critical temperature $T_c$ of the deconfinement phase transition.

The $\theta$-term in the magnetic string worldsheet Lagrangian is induced by CS term

$$L_{CS} = \int d^3 x \ C_1 \wedge F$$

(8) 

that is configurations with the flux on the worldsheet amount to the nontrivial 4d topological charge. It was also argued that the magnetic strings amount to the negative contribution to the total energy of plasma at $T > T_c$ [4]. It could explain the negative-sign contribution of the lattice magnetic strings into the energy of plasma [26]. Because of the instability of the "thermal" cigar magnetic string becomes effectively particle-like object in the Euclidean 3D [4], in agreement with the lattice studies [27].

D2 domain walls.  
Turn now to the discussion of the D2 domain walls. Let us emphasize from the very beginning that to consider the stable infinite domain walls the degenerate vacua should exist. On the other hand we expect the single stable vacuum in the pure YM case and QCD. That is the arguments concerning the domain walls should be interesting in two aspects. First, there are metastable vacua whose energy density differs from the density of the true one by the terms $O(1/N)$ that is they are almost stable at large N. One can also consider the domain wall balls when the configuration is stabilized by the domain wall tension.

There are two types of domain walls in $R^3$ built from D2 branes. Consider first a D2 brane localized in the $x_4$ coordinate. It corresponds to a domain wall in 4D and has no $\theta$ dependence. The theory on the domain wall involves the periodic real scalar field which corresponds to the position of the D2 brane on the $x_4$ circle as well as a scalar corresponding
to its radial coordinate. Its tension is small in the deconfinement phase and it behaves as
the string in the 3d effective description. It has no $\theta$ dependence.

The second type of D2 S-domain walls extended in $x_4$ involves a nontrivial $\theta$ dependent
term. Because of the unbroken electric $Z_N$ symmetry in the confinement phase such domain
walls are expected to exist in N-tuples in this phase symmetrically on the $\tau$ circle. The
worldsheet theory in the deconfinement phase involves only one real scalar corresponding
to its radial coordinate. These D2 domain walls may play an important dynamical role
supporting the constituents with fractional topological charges, see Section IV.

**Space filling D2 brane**.

One could also consider the D2 branes localized both in $\tau$ and $x_4$ directions. Such space-
filling D2 branes most probably are expected to exist in N-tuples in both phases because in
each phase the D2 brane has one unbroken $Z_N$ symmetry. Hence the effective gauge theory
should have SU(N) gauge theory in both phases. These branes could play an important
role in the effective 3D description of the deconfinement phase. Their worldvolume theory
naturally involves one complex and one real periodic scalars.

**D2-\bar{D}2 pair**.

One could also discuss the D2 brane extended along the radial coordinate. Such a config-
uration is an analogue of the D8 brane in Sakai-Sugimoto model which is extended along
the radial coordinate and has U-shape form in the chirally broken phase. In the holographic
QCD case one actually has $D8 - \bar{D}8$ pair which connectness indicates non-vanishing of the
chiral condensate. In the case of the U-shaped D2 brane we have no flavor brane hence
the chirality can not be defined in the conventional way. However, there is a configuration
which is readily prepared to provide the chiral condensate if D8 brane is introduced into
the system. If such U-shaped D2 brane is extended along $\tau$ it behaves as string while in
the opposite case as the domain wall. In both cases the tension of the object is finite. It
is tempting to speculate that some kind of the chiral symmetry breaking happens in pure
gauge theory (without flavor fermions) being localized at lower dimensional defects rather
than in the entire space.

It is also tempting to speculate that some of the D2 branes discussed in this subsection
could be mapped into the low-dimensional, chirality-related structures observed on the
latices.

C. D4 branes

\underline{D4 particle}

There are several possible embeddings of D4 branes. One possibility concerns D4 wrapped around $S^4$ and extended along the Euclidean time $\tau$. The familiar example of such wrapping in the QCD like geometry \[2\] has the interpretation of baryon if matter fields in the form of D8 branes are present in the system. The key point here is that due to the CS term

$$\int d^5x C_3 \wedge F \sim N_c$$

the “electric charge” $N_c$ is induced on the D4 brane that is one has to add $N_c$ open strings. It is a static topologically stable configuration. In the QCD-like case these open strings end on the D8 brane yielding the baryonic state.

In the pure YM case there are no flavor branes that is one has to add additional low-dimensional branes to compensate charge and make a gauge invariant object. The most simple way to achieve this goal is to add $N_c$ D0 branes yielding the D0-D4 open strings. Hence we get the D4 particle which does not feel the $\theta$-term and is well-defined below the critical temperature $T < T_c$.

We can combine the “D4 particle” with “D4 anti-particle” to form a gauge invariant object, see FIG 2. The mass of this object scales as $\sim N_c$ and is much heavier than the usual glueballs. In fact, one can construct gauge invariant objects with any even number of vertexes such that the total charge vanishes. It is a new family of glueballs with mass $\sim N_c V$, where $V$ is the number of D4 and anti-D4 particles which form a desired configuration. It is amusing that such kind of structure in QCD had been previously discussed \[28\] motivated by the discovery of the carbonic Fullerenes $C_{60}$ and $C_{70}$ in 1985, which are nano-scale objects \[29\]. The QCD objects, similar to the carbonic Fullerenes with femto-meter scale were named Buckyballs. It has been also demonstrated that the “magic” numbers for Buckyballs are $V = 8, 24, 48, 120$ which correspond to the most symmetric, and likely, most stable configurations \[28\]. The properties of this configuration are not sensitive to $\theta$. The possibility to discover such kind of configurations at RHIC was discussed in \[28\].
FIG. 2: Buckyballs with $N = 3$ and $V = 8, 24, 48, 120$ from [28]. The construction combines “D4 particle” with “D4 anti-particle” to form a gauge invariant object with zero baryon charge. The mass of this object scales as $\sim N_c$.

**D4 instanton.**

If we consider wrapped D4 brane extended along $x_4$ we get a new-object, "D4 instanton" which is to be distinguished from the “D4 particle” discussed above. The origin of this term is due to its similarity in the 4D Euclidean space-time to the canonical instanton (or caloron at $T \neq 0$). This object tends to condense below the phase transition and is well defined above the transition point, similar to the instanton. It carries a nontrivial $\theta$ dependence and the corresponding contribution to the action from the single "D4 instanton" looks as follows

$$\delta S \propto \theta \int Tr F \wedge F \propto C_1$$

(10)

Due to the background flux $dC_3$ through $S^4$ one has

$$N_c \int dx_4 C_1$$

(11)

term in the action implying that the D4-instanton worldvolume is populated by N D0 instantons which provide the topological charge N in D4 worldvolume theory. Due to the unbroken electric $Z_N$ in the confinement phase one could expect the N-tuples of D4-instantons to exist. The nature of large factor $N_c$ in both equations (11) and (9) is one and the same, namely the background flux $dC_3$ through $S^4$ which is proportional to $N_c$. 
However, the physical interpretation for these two cases is quite different: in the first case it is the mass of the particle which is $\sim N_c$, while in the second case it is the action of $N_c$ different instantons accompanied by $4N_c$ zero modes each. It is tempting to identify this D4- instanton with the configuration consisting of $N_c$ different calorons with maximally nontrivial holonomies\(^1\). As is known, exactly the configuration consisting $N_c$ different calorons provides an infrared finite contribution to the partition function \([30]\).

**D4-$\overline{D}4$ U-shaped pair.**

One can also consider the U-shaped D4 brane extended along the radial coordinate. If it wraps $S^4$ it is an instanton-like object which however does not carry any $\theta$ dependence. Since there is in fact a connected $D4 - \overline{D}4$ pair one could say that such objects amount to the chiral symmetry breaking "at a point". On the other hand one can consider U-shaped D4 brane localized at $S^4$. Such object is a space-time filling brane which provides a kind of homogeneous "chiral symmetry breaking" in pure YM theory.

**D. D6 branes**

**D6 string.**

Let us turn to D6 branes. Consider first the pure YM case at large $N_c$. If D6 is wrapped around $S^4 \times x_4$ it behaves as the string in the space-time whose tension is defined by the scale of $S^4$. Due to the wrapping around $S^4$ the string carries a CS term generated on its worldsheet from the CS term

$$\int d^7x C_3 \wedge F \wedge F$$

which reads as $N_c \int d^3x A \wedge F$. In the confinement phase there is a nontrivial holonomy along $x_4$ represented by $W(R)$, see \([6]\), hence the effective 2d $\theta$ term on the D6 string is induced. Note that the induced $\theta$ term on the D6 string is proportional to $N_c$, somewhat similar to the situation discussed in \([31]\) for the magnetic strings in $N = 1(\ast)$ theory.

Due to the wrapping around $x_4$ it carries intrinsic $\theta$ dependent term

$$\int d^7x C_1 \wedge F \wedge F \wedge F$$

\(^1\) Instanton at $T \neq 0$ becomes a caloron with a generically nontrivial holonomy \([25]\).
To provide the $\theta$ dependent contribution from this term the topological Chern number $c_3(F)$ should be nontrivial. It follows from the D2 branes on the D6 worldvolume. Hence we see that the interesting "composite" D6-D2 string has $\theta$ dependent contributions from the both components. Such D6 strings according to our standard arguments are individually unstable and large number of them have tendency to condense at small temperatures $T < T_c$. The object is well defined at large temperatures, $T > T_c$ and has finite tension. The interpretation of such kind of objects is far from obvious, and the role they play in physics is also unclear at the moment.

One can also consider the U-shaped $D6-\bar{D}6$ pair in the confinement phase corresponding to the string with the finite tension. Due to the connectness of D6 brane it localizes the chiral symmetry breaking on its worldvolume.

**D6 domain wall.**

If D6 brane wraps around $\tau$ it behaves as the domain wall which is a source of the corresponding RR-form. Such a configuration has been interpreted in ref. [5] as the domain wall which separates different metastable vacua known to exist in gluodynamics at large $N_c$. Its worldvolume theory on the domain wall involves the conventional CS term and has no $\theta$ dependent term.

**IV. COMPOSITE DEFECTS**

In this Section we present a few examples of composite defects which exhibit interesting features. Some of them may play a crucial role in understanding of the dynamics.

**D0-D2.**

First, we want to address the following question: what happens to instantons in the confined phase. Naively, one could think that as the metric takes the geometry of a cigar in $(x_4, u)$ plane at $T < T_c$ the system becomes unstable, and therefore, there is no subject for the discussions as instantons simply disappear from the system. However, as we discussed before, one should speak about effectively zero action for formation of such kind of objects. Therefore, numerous number of these objects can emerge in the system without any suppression. In fact, in [16] it has been argued that this is precisely what is happening when
one crosses the phase transition line from above.

Now, in order to investigate what kind of objects may emerge when the phase transition is crossed from above, we add the D2 domain walls (discussed in section IIIB) localized at some points along $x_4$ coordinate. In this construction an object with a fractional topological charge $1/N_c$ may emerge. Indeed, one can follow the construction of ref. [32] for SUSY case when $N_c$ D2 branes located symmetrically split the instanton into $N_c$ constituents stretched between pairs of domain walls. Each constituent has fractional instanton number $1/N_c$ as well as the fractional monopole number and has no reason to condense. In our system we have precisely appropriate D2 branes which are needed for this construction. These monopoles are instantons in the 3d gauge theory on the D2 worldvolume theory which involves the scalar corresponding to the position of D2 branes on the cigar. As we mention previously in Section IIIA these magnetic monopoles may play an important role in the region close to the phase transition $0 < |T-T_c|/T_c \leq 1/N_c$.

\[ \text{D6-D4} \]

There are several configurations involving composite D6-D4 defects. The first one to be mentioned is the combination ”D6 string-D4 instanton”. Since the D4 instanton shares all coordinates with D6 string it is melted into the flux on the string of constant ”electric” field. Another example of the melting concerns the combination ”D6 domain wall-D4 particle” when the D4-particle delocalizes on the domain wall into the flux. It is interesting to note that since in the holographic QCD the D4 particle is identified with the baryon upon melting we get a domain wall with the baryonic density. The defect is well defined in the confinement phase.

Another interesting possibility concerns the combination ”D6 domain wall-D4 instanton”. In this case a fractional D4 instanton can emerge if there are several domain walls localized at different positions at $x_4$ and D4 instanton can be stretched between a pair of domain walls in the $x_4$ direction yielding a monopole-like objects on the domain-wall worldvolume.

\[ \text{D2-D4} \]

An interesting situation happens if we consider the configuration of D2- string and D4-particle localized in $x_4$. In this case the magnetic D2 string can be stretched between two D-particles and therefore does not wrap the $x_4$ circle. Hence it has finite tension equal to the distance $\delta x_4$ between two D4-particles and does not condense in the confinement phase.
This configuration carries fractional topological charge and is $\theta$ dependent. The D4-particles acquire magnetic charges where the flux of the magnetic string ends on.

In the case of D2-domain wall and D4-instanton opposite situation can happen. The D4-instanton worldline can be split between two D2-domain walls localized at different $x_4$ coordinates. Such configuration carries fractional topological charge as well.

**D2-D6**

The simplest configuration of such type is "D6 string- D2 string". That is we have composite string object with additional "charge" since the D2 induces instanton-like charge on the D6-brane worldvolume. Such a composite string is unstable in the confinement phase and well defined in the deconfinement phase. Another combination "D6 domain wall- D2 string" can be stable in the confinement phase if there are several domain walls localized at different positions in $x_4$. The same can be said about the configuration of "D2 domain wall-D6 string" with several D2 walls.

**V. DEFECTS IN HOLOGRAPHIC QCD**

In this Section we discuss defects in the holographic QCD when matter fields are included by adding $N_f$ U-shaped D8 branes \[2\] in the probe approximation. This case can be considered as a particular example of the composite defects in pure YM theory. To study defects in holographic QCD we shall add some additional probe branes of different dimensions. In what follows we mention only a few effects which are specific for theory with the fundamental matter.

First, we can add U-shaped D6 branes parallel to the D8 branes. From the 4d viewpoint they are unstable strings. Indeed the D6 branes share all worldsheet coordinates with the D8 branes, hence there are tachyonic modes in the spectrum of D8-D6 open strings and the D6 brane melts in the D8 worldvolume yielding a flux of the flavor gauge field. Since the D6 branes get delocalized they do not provide string-like localization of the chiral symmetry breaking.

Another interesting example concerns the D4 instanton in holographic QCD extended along $x_4$ or radial coordinate. To estimate its contribution into the partition function remind that there is CS term on the D8 brane worldvolume multiplied by $N_c$. Since U-shaped D4
instanton shares all coordinates with the D8 branes it induces a nontrivial contribution into the CS part of the action which reads as follows

$$\delta S_{CS} = N_c \int du A_u \int d^4Tr F \wedge F$$  \hspace{1cm} (14)$$

where we assume that $U(1)_A$ field $A_u$ is space-time independent. It can be interpreted as the constant mode of $\eta'$ meson since in the SS model it is identified as $\int du A_u(u, x)$. Note that that the constant mode of $\eta'$ mode can be thought of as the effective $\theta$ term hence the total contribution reads as $\theta_{eff} N_c k$ where $k$ is the instanton number in the flavor gauge theory. Such U-shaped D4 instanton is well defined at any temperature since it does not wrap around any compact coordinate and one could speak about the point-like contribution to the chiral symmetry breaking.

One can also discuss fractional flavor D4 instantons. To this aim the flavor branes have to be placed at different positions at the dual temporal circle. This can be achieved by switching on chemical potentials which correspond to nontrivial temporal holonomies of the flavor gauge fields. The eigenvalues of the flavor holonomy around the temporal circle provide the positions of the D7 branes on the dual circle. Hence the worldline of the D5 brane on the dual circle can split and we get $N_f$ fragments of D5 brane stretched between $N_f$ D7 branes which carry the flavor ”magnetic” and fractional instanton charges. The system can be described in QFT terms as a set of $N_f$ ”monopoles” with the total instanton charge $Q_{\text{inst}} = 1$ and the total monopole charge zero, similar to the canonical caloron with nontrivial temporal holonomies, see for reviews [33, 34] and references therein. Since we are working in the probe approximation $N_f \ll N_c$ the action on each ”monopole” is proportional to $N_C$ and therefore these defects are suppressed at large $N_c$.

Another possible phenomenon concerns a peculiar manifestation of the Myers effect in the holographic QCD. It is known that the following configuration: two parallel D4 branes + D0 branes localized on the D4 branes + D0-D0 open strings, is unstable and decays into the so-called dyonic instanton [36]. That is this configuration of instantons decays into the circular D2 brane stretched between parallel D4 branes with electric and topological charges as well as angular momentum which stabilizes the system. On the D4 worldvolume one gets a magnetically charged ring.

In our context, we can consider the set of D8 and D4 branes representing the baryons in the space-time [? ]. We assume that the worldvolume of the D4 brane is $S^4 \times \tau$, that is
both type of branes are localized at the $x_4$ coordinate. We could assume that the D8 branes are generically localized at different values $x_{4k}$ where $k + 1, \ldots N_f$, and the ”baryonic” D4 branes are localized on the D8 branes. Consider two baryonic D4 branes and connect them by an open string which carries in the spectrum of excitations the gauge boson of the flavor group- $\rho$ meson. Similar to the D4-D0-F1 case we expect that the D4 brane is expanded into a D6 brane with baryonic density and the F1 string is melted into the isotopic charge amounted from the initial $\rho$-meson. Hence finally we could expect that the configuration with the baryonic charge larger than one gets delocalized into the ”baryonic ring” carrying the isotopic charge. Note that it is known in the Skyrme model that the $B=2$ state has a torus like ground-state geometry [37], in agreement with our arguments above. Note that such a configuration does not involve wrapping around $x_4$, that is it is well defined at $T < T_c$.

VI. CONCLUSIONS

In this note we demonstrated that the holographic description of the pure YM or QCD-like theories implies existence, at least classically of a plenty of defects of different codimensions. We have tried to argue that their existence is insensitive to details of the metric. However the analysis is certainly oversimplified and we have not aimed at deriving the defects properties in detail. We have seen that various types of strings and domain walls and some more exotic composite objects are emerging.

A few claims seem to be quite generic. If the defect tends to condense (have small tension vanishing classically) at small temperatures it becomes tensionful and well defined above the phase transition. On the other hand, all the defects apart from the S-branes tend to loose one Euclidean dimension above the critical temperature. The $\theta$ dependence of the defect’s worldvolume actions is present in the ”condensing brane” below the phase transition and can be defined on such defects above the transition point as well on a single defect. This is an analogue of the instanton solution of the U(1) problem via the Witten-Veneziano mechanism below the transition point and via the t’Hooft mechanism above this point. Our analysis implies that a similar change of mechanisms happens for defects of different dimensions as well.

The theory above the phase transition almost immediately becomes three-dimensional because of the cigar-type instability. This fits well with the lattice studies.
In particular, in holographic description we identified a few very interesting objects such as heavy buckyballs (D4 particles) whose masses scale as $\sim N_c$ (see section IIIIC) or D4 instantons whose action scales as $\sim N_c$. While such objects have been discussed previously in the literature within QFT, their future study using the holographic description may shed a new light on their nature. Another interesting example deserves to be mentioned is the holographic description of the objects with fractional topological and magnetic charges (section IV). Such objects have been discussed within QFT in late 70s. Future study of these objects may provide with a key to understand the QCD vacuum structure and the nature of the phase transition.

There are many questions we have only touched upon. In particular, it would be highly interesting to understand better the role of the second order parameter ”dual” to the Polyakov loop and the duality between the corresponding pairs of domain walls which gets interchanged at the phase transition. Our analysis suggests that it is probably reasonable to discuss the chiral symmetry breaking in pure YM theory induced by U-shaped defects. At first glance it might look strange, but ”chiral symmetry” of the gauge boson can be defined similar to fermions. The order parameter for such a ”chiral symmetry breaking” could be similar to the one recently discussed in [38]. We did not discuss the defects involving NS5 branes since it is more natural to discuss such issue upon lifting of IIA setup to the M-theory. In that case the corresponding defects involve M2, M5, KK particles and KK monopoles.

Acknowledgments

We thank The Galileo Galilei Institute for Theoretical Physics for the organization of the workshop “Non-perturbative methods in strongly coupled gauge theories” where this projected was initiated.

ARZ was supported, in part, by the Natural Sciences and Engineering Research Council of Canada. The work of A.G. was supported in part by grants INTAS-1000008-7865 and PICS-07-0292165. V.I.Z. would like to thank the Laboratoire de Mathematiques et Physique Theorique at UNiversité Francois Rabelais, Tours, France for kind hospitality during the final
stages of working on the project.
