Abstract

We present an analysis of the longitudinal $\bar{\Lambda}_0$ polarization in ultra-relativistic heavy-ion collisions. The polarization of $\bar{\Lambda}_0$'s coming from the decay chain $\Xi \rightarrow \Lambda_0 + \pi$ exhibits a very well differentiated behavior depending on the production region of the primordial $\Xi$'s. This effect reflects the different values of the $N_{\Xi}/N_{\bar{\Lambda}_0}$ ratio in the QGP region, where nucleon-nucleon interactions take place in a hot and dense environment, and the peripheral region, in which ordinary nucleon-nucleon interactions occur. An increase in the longitudinal $\bar{\Lambda}_0$ polarization signals a strangeness enhancement which is thought as a property of the QGP phase.

1 Introduction

In nuclear collisions at relativistic and ultra-relativistic energies, it is expected a phase transition from ordinary nuclear matter to a Quark Gluon
Plasma (QGP), which should be observed when sufficiently high baryonic densities and/or temperatures be achieved in the collision. In order to identify this phase transition, a number of experimental observables, namely $J/\Psi$ suppression, strangeness enhancement, fluctuations in particle ratios, flow patterns, etc. have been proposed [1].

In particular, it has been argued that the strangeness enhancement in hot and dense regions of nuclear matter would lead to an abundant formation of multi-strange baryons and antibaryons, providing them a key information about the QGF formation [2]. Indeed, detailed calculations [3] predict that the abundance of $\bar{\Xi}(\bar{s}\bar{q}\bar{q})$ should be enriched to about half the abundance of antihyperons $\bar{\Upsilon}(\bar{s}\bar{q}\bar{q})$ as compared to the $\bar{\Xi}/\bar{\Upsilon}$ ratio seen in nucleon-nucleon interactions. Considering that at $\sqrt{s} = 63$ GeV, $\bar{\Xi}/\bar{\Lambda}_0 = 0.06 \pm 0.02$ [4] in the central rapidity region, then in the presence of QGP, the $\bar{\Xi}/\bar{\Lambda}_0$ would be ten times greater. However, although the $\bar{\Xi}/\bar{\Lambda}_0$ ratio is a quantity which is difficult to establish experimentally, the longitudinal $\bar{\Lambda}_0$ polarization is not and can be used to get a measurement of the above mentioned ratio [2].

At this point it is useful to remember that $\Xi$ decays into $\Lambda_0 + \pi$ with a branching fraction of about 99 % and that the weak decay polarizes the $\Lambda_0$ spin longitudinally. This means that all the longitudinally polarized $\Lambda_0$ are associated with the primordial abundance of $\Xi$. Note also that $\Omega^+$ have a little influence on the particle abundances and, in particular, over their polarizations [2]. In fact, the STAR Collaboration [4] measured $N_\Omega/N_{\Xi^+} \sim 0.16$, where $N_\Omega$ refers to the total number of $\Omega^-$ + $\Omega^+$. Furthermore, the polarization of $\Lambda_0$'s coming from $\Omega^+ \rightarrow \Lambda_0 + K^+$ (BR $\sim 68\%$) is a factor of 5 lower than polarization of $\Lambda_0$'s coming from $\Xi \rightarrow \Lambda_0 + \pi$ while the polarization of $\Lambda_0$'s coming from the decay $\Omega^+ \rightarrow \Xi + \pi$ (BR $\sim 23\%$ and BR $\sim 9\%$ for the $\Xi^0$ and the $\Xi^+$ decay modes respectively) and the subsequent decay of the $\Xi$ into $\Lambda_0 + \pi$ is still lower by a factor of $\sim 20$. This situation is expected to be maintained at the energy where QGP formation takes place (see also discussions in Refs. [2, 3]).

The $\Lambda_0$ polarization can be defined in terms of the so called up-down asymmetry of the $\Lambda_0$ decay with reference to the plane normal to the $\Lambda_0$ momentum. Thus [2]

$$\frac{N_u - N_d}{N_u + N_d} = \frac{1}{2} \alpha_\Lambda p_\Lambda \alpha_\Xi,$$  \hspace{1cm} (1)

where $p_\Lambda = \alpha_\Xi = -\alpha_\Xi$ is the $\Lambda_0$ polarization and $\alpha_\Lambda$ is the $\Lambda$ decay parameter. From data tables $\alpha_\Lambda = -\alpha_\Lambda = 0.642 \pm 0.013$ and $\alpha_\Xi = 0.413 \pm 0.022$ (0.455 ±
0.015) for \( \Xi^0 (\Xi^-) \). Hence the total up-down asymmetry for all the neutral \( \Lambda_0 \) events is

\[
\frac{N_u - N_d}{N_u + N_d} = \frac{1}{2} \alpha_\Lambda \alpha_\Xi \gamma,
\]

where \( \gamma = \frac{N_\Xi}{N_{\Lambda_0}} \).

Eq. (2) shows that in ordinary nucleon-nucleon interactions at the ISR energies, the up-down asymmetry should be of the order of \(-0.008\) while in hot and dense nuclear matter it should amount to something about \(-0.07\), which is an effect of one order of magnitude and that could be measured in experiments.

Of course, all of the above argumentation can be applied to \( \Lambda_0 \) and \( \Xi \)'s, but in this case, many of the \( \Lambda_0 \)'s should be mere fragments of nucleons going into \( \Lambda_0 K \), giving a less clear signal.

In the interaction region of a heavy-ion collision it is expected to have a core of hot and dense nuclear matter - possibly QGP - surrounded by a region in which ordinary nucleon-nucleon interactions take place (see Fig. 1). These regions, as it is shown in the following sections, can be mapped by measuring the \( \Lambda_0 \) polarization as a function of the impact parameter, \( b \), and transverse momentum, \( p_T \). What is expected is a plot displaying a polarization approximately constant and of the order of \(-0.07\) in the hot and dense region surrounded by a region in which the polarization is, again constant, and of the order of \(-0.008\), corresponding to the periphery, where ordinary nucleon-nucleon interactions occur.

The paper is organized as follows. In Section 2 we study the behavior of the \( \frac{N_\Xi}{N_{\Lambda_0}} \) ratio in both the low and high nuclear density regions. In Section 3 we calculate the \( \Lambda_0 \) polarization as a function of the impact parameter and transverse momentum, and Section 4 is devoted to conclusions and final remarks.

## 2 The \( \frac{N_\Xi}{N_{\Lambda_0}} \) ratio in heavy ion collisions

In the interaction region of the collision of nucleus \( A \) and \( B \), when QGP coexists with the ordinary nuclear matter, the ratio of the number of \( \Xi \) to the number of \( \Lambda_0 \) baryons is given by

\[
\gamma_{A+B} = \frac{N_{\Xi}^{\text{periph}} + N_{\Xi}^{\text{QGP}}}{N_{\Lambda_0}^{\text{periph}} + N_{\Lambda_0}^{\text{QGP}}}
\]
Figure 1: Schematic representation of the reaction $A + B$ and the regions in which $\Xi$’s are produced. In the hot and dense (QGP) region, $\gamma_{QGP} \sim 0.5$ while in the periphery, in which ordinary nucleon-nucleon interactions take place, $\gamma_{\text{periph.}} << \gamma_{QGP}$.

$$\gamma_{A+B} = \frac{N_{\Lambda_0}^{\text{periph.}} \gamma_{\text{periph.}} + N_{\Lambda_0}^{QGP} \gamma_{QGP}}{N_{\Lambda_0}^{\text{periph.}} + N_{\Lambda_0}^{QGP}},$$

(3)

where the quantities labeled $^{\text{periph.}}$ and $^{QGP}$ refer respectively to the number of $\Lambda_0$ and $\Xi$ in each region. As long as the dependence on the impact parameter, $b$, and transverse momentum, $p_T$, of $N_{\Lambda_0}$ is different in the QGP than in the peripherical region, $\gamma_{A+B}$ must be also dependent on $b$ and $p_T$. In fact, in the same way as the longitudinal polarization of $\Lambda_0$’s does, it should provide a map of the interacting region in which the peripherical and QGP zones are displayed. Note, however, that the only dependence on $b$ and $p_T$ in $\gamma_{A+B}$ arises from the dependence on $b$ and $p_T$ in $N_{\Lambda_0}^{\text{periph.}}$ and $N_{\Lambda_0}^{QGP}$ since $\gamma_{\text{periph.}}$ and $\gamma_{QGP}$ are expected to be approximately constant. 

\[\]
2.1 $N_{\Lambda_0}(b,p_T)$ in the peripherical region

The $N_{\Lambda_0}^{periph.}$ can be estimated along the lines in Ref. [6]. As stated in [6], and remembering that in ordinary nucleon-nucleon interactions the typical behavior of the production cross section as a function of $p_T$ is an exponential in $p^2_T$, the number of produced $\Lambda_0$'s as a function of the impact parameter and $p_T$ in the collision of nucleus A and B can be written as

$$\frac{d^4 N_{\Lambda_0}^{periph.}}{d^2b \ dp_T^2} = \frac{1}{2} C e^{-a p_T^2} T_{AB}(b), \quad (4)$$

where the $1/2$ is because the number of $\Lambda_0$'s is approximately half the number of neutral hyperons, $C$ is a constant which normalizes the integral over the transverse momentum to unity, and $T_{AB}$ is

$$T_{AB}(z,b) = \int d^2s T_A(z,b) T_B(z,s-b), \quad (5)$$

with $T_A$ and $T_B$ given by

$$T_A(z,s) = \int_{-z/2}^{z/2} dz' \rho_A(z',s), \quad (6)$$

and where the limits of integration over $z$ have to be extended to $[-\infty, +\infty]$. For $\rho_A$, which is the nucleon density per unit area in the transverse plane with respect to the collision axis, we use the standard Woods-Saxon density profile

$$\rho_A(r) = \frac{\rho_0}{1 + e^{(r-R_A)/d}}, \quad (7)$$

with $R_A = 1.1A^{1/3}$ fm, $d = 0.53$ fm [7] and $\rho_0$ fixed by normalization

$$\int dr \rho_A(r) = A, \quad (8)$$

giving $\rho_0 = 0.17$ fm$^{-3}$ in the case of $^{197}$Au, which we shall consider as an example in the following.

We are assuming that each peripheral collision produces final state particles in the same way than in free nucleon reactions. However, in order to exclude the zone where the density of participants $n_p$ is above the critical density $n_c$ to produce QGP, we rewrite eq. (4) as

$$\frac{d^4 N_{\Lambda_0}^{periph.}}{d^2b \ dp_T^2} = \frac{1}{2} C e^{-a p_T^2} \int d^2s T_A(z,b) T_B(z,s-b) \Theta [n_c - n_p(s,b)], \quad (9)$$
where \( n_p(s, b) \) is the density of participants at the point \( s \) and \( \Theta \) is the step function. The density of participants per unit transverse area in the collision of nucleus \( A \) with nucleus \( B \) at an impact parameter \( b \) has a profile given by

\[
n_p(s, b) = T_A(s) \left[ 1 - e^{-\sigma_{NN} T_B(s-b)} \right] + T_B(s-b) \left[ 1 - e^{-\sigma_{NN} T_A(s)} \right],
\]

where \( \sigma_{NN} \) is the nucleon-nucleon inelastic cross section which we take as \( \sigma_{NN} = 32 \) mb. The total number of participants \( N_p \) at an impact parameter \( b \) is

\[
N_p(b) = \int d^2s \ n_p(s, b).
\]

From eq. (9), the number of \( \bar{\Lambda}_0 \)'s coming from the decay chain \( \Xi \rightarrow \bar{\Lambda}_0 + \pi \) is then given by

\[
\frac{d^4N_{\Xi \rightarrow \bar{\Lambda}_0 + \pi}^{\text{periph.}}}{d^2b \ dp_T^2} = \frac{\gamma_{\text{periph.}}}{d^2b \ dp_T^2} \frac{d^4N_{\bar{\Lambda}_0}^{\text{periph.}}}{d^4N_{\bar{\Lambda}_0}^{\text{periph.}}}. \tag{12}
\]

Following Ref. [8], we choose \( n_c = 3.3 \) fm\(^{-2} \) for the critical density. This number results from the observation of a substantial reduction of the \( J/\Psi \) yield in Pb - Pb collisions at the SPS. For the parameter \( \gamma \) in eqs. (4) and (9) there is no published data at the relevant energies, which for LHC should be of about 5 TeV per nucleon. Then we use the value measured by the Hera-B Collaboration [9] in proton-nucleus interactions at 920 GeV, \( \gamma = 2.2 \pm 0.3 \) GeV\(^{-2} \).

\[\text{2.2} \quad N_{\bar{\Lambda}}(b, p_T) \text{ in the QGP region}\]

In QGP, the average number of produced antistrange quarks scales with the number of participants \( N_p^{\text{QGP}} \) in the collision roughly as

\[
\langle \bar{s} \rangle = c N_p^{\text{QGP}}. \tag{13}
\]

Assuming that a \( \bar{s} \) quark will produce \( \Xi, \bar{\Lambda}_0 \) or \( \Sigma_0 \), and taken the number of \( \bar{\Lambda}_0 \) approximately equal to the number of produced \( \Sigma_0 \), we have

\[
\langle \bar{s} \rangle = 2N_{\Xi}^{\text{QGP}} + 2N_{\bar{\Lambda}_0}^{\text{QGP}} = [2\gamma_{\text{QGP}} + 2] N_{\bar{\Lambda}_0}^{\text{QGP}}. \tag{14}
\]
Combining eqs. (13) and (14) we obtain

\[ N_{QGP}^{\bar{\Lambda}_0} = \frac{c}{2\gamma_{QGP} + 2} \left[ N_{p}^{QGP}\right]^2 . \]  

(15)

\[ N_{p}^{QGP}(b) = \int d^2 s \, n_p(s, b) \theta \left[ n_p(s, b) - n_c \right] . \]  

(16)

The eq. (15) represents the behavior of the number of \( \bar{\Lambda}_0 \) as a function of the impact parameter, then we use

\[ \frac{d^4 N_{\bar{\Lambda}_0}^{QGP}}{db \, dp_T^2} = \frac{c}{2\gamma_{QGP} + 2} \left[ N_{p}^{QGP}(b) \right]^2 C' e^{-a' p_T^2} , \]  

(17)

assuming an exponential dependence in \( p_T^2 \) for \( \bar{\Lambda}_0 \) production \[10\]. As for the peripheral \( \bar{\Lambda}_0 \)'s, eq. (17) times \( \gamma_{QGP} \) gives the number of \( \bar{\Lambda}_0 \)'s as a function of \( b \) and \( p_T \) coming from the decay chain \( \Xi \to \bar{\Lambda}_0 + \pi \) in the QGP phase. We use \( c = 0.005 \) \[6\] and read \( a' = 0.67 \) from Ref. \[10\].

In Figs. 2 and 3 we show the behavior of the total (peripheral + QGP) number of \( \bar{\Lambda}_0 \)'s as a function of the impact parameter for different values of \( p_T \) and as a function of \( p_T \) for several values of \( b \) respectively.

### 3 \( \bar{\Lambda} \) polarization in heavy ion interactions

The up-down asymmetry is then given by eq. (2) with \( \gamma_{eff} \) as given in eq. (3) and shown in the left side of Fig. 4 as a function of \( b \) and \( p_T \). The right side of Fig. 4 shows the behavior of \( \gamma_{eff} = N(\Xi)/N(\bar{\Lambda}_0) \) defined in eq. (3) as a function of \( b \) and \( p_T \). As can be seen, the \( \bar{\Lambda}_0 \) polarization exhibits a dramatic change as the impact parameter becomes bigger than a critical value, starting from which the QGP region suddenly vanishes. From this value on the polarization reaches the characteristic value seen in ordinary nucleon-nucleon interactions. Conversely, at high \( p_T \) and low \( b \), the polarization shows the behavior expected in the hot and high density region where QGP takes place. This reflects the characteristic increase in the \( N_\Xi/N_{\bar{\Lambda}_0} \) expected when QGP be formed. Another interesting feature of the longitudinal \( \bar{\Lambda}_0 \) polarization is the dependence on \( p_T \) due to the different \( p_T \) dependence of \( \bar{\Lambda}_0 \) production in the peripheral and QGP region.
However, in relativistic heavy-ion collisions, there are several effects which can modify the $\bar{\Lambda}_0$ polarization and have to be taken properly into account. These are i) $\bar{\Lambda}_0$'s produced by secondary pion-nucleon scattering, ii) secondary scattering of $\bar{\Lambda}_0$'s with nucleons in the interaction region and iii) spin-flip in secondary interactions of the $\bar{\Lambda}_0$'s. $\bar{\Lambda}_0$'s coming from secondary pion-nucleon interactions will have a characteristic low momentum signature and can be eliminated from analysis by setting kinematical constrains in the reconstruction of data, therefore excluding them from the polarization analysis. Spin-flip effects in polarization, which are associated to spin-spin interactions among the $\bar{\Lambda}_0$ and the surrounding particles, are characterized by a polarization transfer coefficient which express the final polarization in terms of the initial one as

$$P' = DP.$$  \hspace{1cm} (18)

However, due to the lack of experimental information at the range of energies of interest, we will omit this effect from our analysis (for a more detailed analysis and Refs., see Ref. [6]). Secondary scattering of $\bar{\Lambda}_0$'s with nucleons in the surrounding nuclear environment will produce a momentum shift that
can be characterized in terms of a sequential model. The final effect will be that, a $\bar{\Lambda}_0$ produced with an initial $(p_L, p_T)$, after multiple-scattering, in the high energy limit, will have an average momentum \[ \langle p_L \rangle = p_L e^{-I\bar{N}(b)} \]
\[ \langle p_T \rangle = p_T e^{-I\bar{N}(b)} \cos \left[ \Gamma \sqrt{\bar{N}(b)} \right], \tag{19} \]
where $I = 0.2$ is the inelasticity coefficient, $\Gamma = 0.01$ is the average dispersion angle in each collision and $\bar{N}(b)$ is the average number of $\bar{\Lambda}_0$ collisions in the nuclear medium,
\[ \bar{N}(b) = \sigma_{\bar{\Lambda}_0N}^{\text{tot}} T_A(b/2), \tag{20} \]
where $\sigma_{\bar{\Lambda}_0N}^{\text{tot}} = 1.4 \text{ mb} \[9\]$, taken from proton-nucleus interactions at 920 GeV. This effect is shown in Figure 5 where the polarization as a function of $p_T$ is displayed for several values of $b$ before and after the momentum shift due to multiple scattering. Note also that, for low $p_T$, the polarization takes the value corresponding to that expected in ordinary nucleon-nucleon interactions, a behavior which is more evident as $b$ grows. Conversely, at high $p_T$ and low $b$, the polarization reaches the value expected in the QGP phase.
Figure 4: Left: $\Lambda_0$ polarization as a function of $b$ and $p_T$ as defined in eq. 2. We used $\gamma_{\text{perip.}} = 0.06$ and $\gamma_{QGP} = 0.5$ to obtain the plot. Right: $\gamma_{\text{eff}} = N(\Xi)/N(\Lambda_0)$ as a function of $b$ and $p_T$ as defined in eq. 3. Note that this plot is rotated by 180° with respect to the plot of the polarization for a better visualization. The maximum of $\gamma_{\text{eff}}$ correspond to the minimum of the $\Lambda_0$ polarization.

4 Final remarks and conclusions

In conclusion, we have shown that the longitudinal polarization of $\Lambda_0$ in heavy-ion relativistic interactions presents a dramatical change with $N_{\Xi}/N_{\Lambda_0}$ in the transition from the expected QGP region to the peripherical one. This effect, which can be easily measured in the laboratory can help to unveil one of the signals of the transition to the QGP phase, namely the strangeness enhancement and the consequent increase in the multistrange baryon formation. Notice that the longitudinal polarization of the $\Lambda_0$ in the low $b$, high $p_T$ region gives direct access to the measurement of the $\gamma_{QGP}$ ratio. It is simply the quotient of the polarization by $\alpha_{\Lambda_0}^2/2$. Conversely, in the high $b$, high $p_T$ region, the $\Lambda_0$ longitudinal polarization gives the $\gamma_{\text{periph.}}$ ratio, which is not easily measured in experiments. It is interesting to note that, the momentum shift due to multiple-scattering of $\Lambda_0$’s in the nuclear medium produces a small increase in the polarization as a function of $p_T$ in the low momentum region.
Figure 5: $\Lambda_0$ polarization as a function of $p_T$ at several values of the impact parameter. Full line shows the polarization before the momentum shift due to multiple scattering in the nuclear medium, dashed line shows the polarization after the momentum shift.

Another possible observable which would exhibit strong changes in the presence of the QGP phase is the transverse polarization of the $\Lambda_0$’s [6, 12]. However, in this case it is expected a decrease of its value with respect to what happens in p-p interactions since transverse polarization is related to the production mechanisms of the $\Lambda_0$.
