Additional index words. embryo growth potential, cold stratification, physiological dormancy, sulfuric-acid scarification, warm stratification

Abstract. Pomegranate is an important fruit crop cultivated in many countries, and development of new cultivars depends on the plant breeders being able to produce plants from seeds. Poor quality and low yield of cultivars are widespread problems that greatly restrict development of the pomegranate industry. Our purpose was to gain a better understanding of the seed dormancy-breaking and germination requirements of four cultivars of pomegranate from Xinjiang Province, China, which would be useful in improving old cultivars and developing new ones. Fresh pomegranate seeds incubated on moist filter paper imbibed water, but they germinated to only 16% to 20%. Sulfuric acid scarification, cold stratification, and warm followed by cold stratification significantly increased germination percentages. Seeds soaked in concentrated H2SO4 for 40 minutes followed by cold stratification for 2 months germinated to 65%, and those warm stratified for 1–3 months followed by cold stratification for 2 months germinated to 75% to 80%. Seeds of pomegranate have nondeeph physiological dormancy (PD).

Pomegranate [Punica granatum L. (Lythraceae)] is believed to have originated in the southern Caspian region and northeastern Turkey, and the Mediterranean Basin is an important diversification center of the species (Halilova and Yildiz, 2009; Levin, 1994). Today, it is extensively cultivated in Afghanistan, Egypt, Italy, India, China, United States, Chile, Spain, and Turkey (Stover and Mercure, 2007), and in Turkey in the Mediterranean, Aegean, and southeastern Anatolia regions (Ercisli, 2004; Ozgen et al., 2008). Pomegranate was introduced to China 2000 years ago, and famous production areas include Lintong in Shanxi Province, Zaozhuang in Shandong Province, Huaixian in Anhui Province, Huili in Sichuan Province, Mengzi in Yunnan Province, and Kashgar in Xinjiang Province (Wang et al., 2010). Although some crop species can be propagated vegetatively, development of new cultivars depends on the plant breeder being able to produce plants from seeds. Pomegranate is a shrub or a small tree widely planted in both tropical and subtropical areas (Wang et al., 2013). Its roots, bark, fruit juice, and dried fruit peel contain abundant anthocyanins and/or hydrolysable tannins that have strong antioxidant (Chidambara et al., 2002), antitumor (Aliq et al., 2005; Hora et al., 2003), and hypolipidemia (Huang et al., 2005) activities. In China, pomegranate is an important crop in six provinces, with about 238 cultivars (Feng and Chen, 2000). However, there are widespread problems with pomegranate cultivars, including poor quality and low yield, which greatly limit the development of the pomegranate industry (Gulimire et al., 2003). Thus, improvement of old cultivars and development of new ones are of great significance (Mars, 2000).

The purpose of our study was to gain a better understanding of the dormancy-breaking and germination requirements of pomegranate seeds to facilitate growing genetically diverse plants for selection of new cultivars. Previous studies have shown that cold stratification, soaking, or both in concentrated H2SO4 can increase the germination percentage of seeds of this species (Gokturk et al., 2012; Olmez et al., 2007; Piotti et al., 2003; Rawat et al., 2010; Riley, 1981; Yucedag and Gultekin, 2009). However, no studies have been conducted on seed dormancy and germination of cultivars that grow in the cold desert region of Xinjiang Province in northwest China. Cultivation of pomegranate is concentrated in southern Xinjiang, particularly in Kashgar, Hotan, and Turpan (Gulimire et al., 2003). Four cultivars were chosen from these three production areas, based on volume of sales and popularity among the people, as our study material. We tested the effects of afterripening in dry storage at room temperature and at 4 °C, sulfuric acid scarification, treatment with gibberellic acid (GA3), cold (moist) stratification, acid scarification plus cold stratification, and warm stratification followed by cold stratification on breaking seed dormancy in the four Xinjiang cultivars Kashgar Akeqishiliu (I), Yecheng Suanshiliu (II), Hotan CeLe1#shiliu (III), and Turpan Suanshiliu (IV) from Kashgar, Kashgar, Hotan, and Turpan, respectively.

Materials and Methods

Seed collection and handling. Freshly matured fruits of cultivars Kashgar Akeqishiliu (I) Yecheng Suanshiliu (II) Hotan CeLe1#shiliu (III), and Turpan Suanshiliu (IV) were collected in Xinjiang Province in Nov. 2012 and 2013. The annual average temperature in the Tafeguard and Turpan basins in Xinjiang is 14.1 and 15.0°C, respectively, and these are the average highest annual temperatures in Xinjiang (Yu and Liu, 2007). The highest average monthly temperatures in Kashgar, Hotan, and Turpan are 25.5, 26.5, and 32.5 °C (July), respectively, and the average lowest temperatures are −5.5, −4, and −7.5 °C (January), respectively.

Fruits were stored dry at room conditions in Xinjiang for 4 d, and then transported to Beijing, where seeds were separated from the fruits, washed, and stored in cloth bags under ambient laboratory (room) conditions until used in experiments. Tetrazolium chloride tests showed that nearly all fresh seeds and about 95% of the nongerminated seeds in the various germination studies were viable. A preliminary germination test showed that 25/15 °C is the optimum temperature regime for germination, and thus this temperature regime was used in all germination tests.

Morphological characteristics of seeds. One-hundred mature, well-developed seeds of each of the four pomegranate cultivars were selected haphazardly, and their color and shape observed. Length and width of each seed also were measured using digital calipers. Ten replications of 100 seeds of each of the four cultivars were weighed (0.0001 g) using an electronic balance.
**Water absorption.** Water absorption (imbibition) was monitored for four replications of 100 fresh seeds of each cultivar. Seeds of the four pomegranate cultivars were placed on filter paper moistened with distilled water in 9-cm-diameter petri dishes and kept at laboratory conditions. At time 0 and after 5, 10, 20, and 30 min and 1, 3, 5, 8, 12, 20, 33, 45, 57, 69, and 81 h, each replication of 100 seeds was blotted dry, weighed to the nearest 0.1 mg, and returned to the petri dish. The amount of water taken up by each replication after each imbibition period was calculated using the following equation:

\[ \%Wi = \frac{(Wi - Wf)}{Wi} \times 100 \]

where \(Wi\) and \(Wf\) are the mass of imbibed and nonimbibed seeds, respectively.

**Effect of dry storage at ambient room temperature on dormancy break and moisture content.** Seeds of the four pomegranate cultivars were stored for 0 month (control), 1, 3, 6, 8, and 12 months in a closed cotton bag under laboratory room conditions. After each period of storage, four replications of 25 seeds each were incubated in petri dishes on two sheets of filter paper moistened with distilled water at 25/15 °C in light (light = 12 h each day, \(\approx 100 \mu\)mol m\(^{-2}\) s\(^{-1}\); 400 to 700 nm, cool-white fluorescent light, hereafter light) and in constant darkness for 28 d. Seeds incubated in light were checked daily for germination, but those incubated in darkness were checked only after 28 d to avoid exposing them to any light during incubation.

Moisture content was determined at time 0 (fresh-weight basis) and at monthly intervals for 1 year for seeds of all four cultivars stored in the laboratory. Five groups of 100 seeds were weighed to the nearest 0.1 mg and then placed in a drying oven at 80 °C for 81 h, each replication of 100 seeds was blotted dry, weighed to the nearest 0.1 mg, and returned to the petri dish. The amount of water taken up by each replication after each imbibition period was calculated using the following equation:

\[ \%MC = \frac{(\text{fresh mass} - \text{dry mass})}{\text{fresh mass}} \times 100 \]

**Effect of dry storage at low temperature on dormancy break.** One week after collection, seeds of each of the four cultivars were placed in a paper bag at 4 °C. After 0, 1, and 2 months of storage, four replications of 25 seeds of each cultivar were incubated at 25/15 °C for 25/15 °C in light and checked for germination daily for 28 d.

**Effect of cold stratification on dormancy break.** Fresh seeds of the four pomegranate cultivars were cold-stratified on moist filter paper in 15-cm-diameter petri dishes in light at 25/15 °C for 1, 2, or 3 months. Then, the seeds were cold-stratified in darkness at 4 °C for 2 months. After cold stratification, four replications of 25 seeds of each cultivar were incubated at 25/15 °C in light for 28 d as described above.

**Effect of warm stratification followed by cold stratification on dormancy break.** Seeds of the four pomegranate cultivars were warm stratified on moist filter paper in 15-cm-diameter petri dishes in light at 25/15 °C for 1, 2, or 3 months. Then, the seeds were cold-stratified in darkness at 4 °C for 2 months. After cold stratification, four replications of 25 seeds of each cultivar were incubated at 25/15 °C in light for 28 d as described above.

**Effect of concentrated sulfuric acid followed by cold stratification on dormancy break.** Fresh seeds of the four pomegranate cultivars were soaked in concentrated H\(_2\)SO\(_4\) for 0 (control), 10, 20, 30, 40, and 50 min, rinsed in distilled water, and then cold-stratified on moist filter paper in 15-cm-diameter petri dishes that were placed in darkness at 4 °C for 0, 4, and 8 weeks. Then, four replications of 25 seeds of each cultivar were incubated at 25/15 °C in light for 28 d as described above.

**Results**

**Morphological characteristics of seeds.** The color and shape of dry seeds of the four pomegranate cultivars are similar, i.e., white and irregular shape. Length, width, and mass of seeds did not differ significantly among ‘Kashgar Akeqishiliu’ (I), ‘Yecheng Suanshiliu’ (II), and ‘Hotan CeLei#shiliu’ (III) (\(P = 0.687\)), but those of ‘Turpan Suanshiliu’ (IV) differed significantly in all three measures from the other three cultivars (\(P < 0.01\)) (Table 1).

**Water absorption.** The curves for water uptake of seeds of the four pomegranate cultivars were similar (data not shown). Thus, for example, for seeds of the Kashgar Akeqishiliu (I) cultivar increase in mass after 5 min and 20 h was 17.1% ± 1.4% and 50.1% ± 1.2%, respectively. Seeds were fully imbibed after 33 h, and the final increase in mass was 53.92% ± 0.08%.

**Effect of dry storage (after-ripening) at ambient room temperature on dormancy break and moisture content.** Three-way ANOVA showed that germination was significantly affected by light condition (\(P < 0.01\)) and storage time (\(P = 0.028\)) (Table 2). There were no significant interactions in germination percentage by cultivars (\(P = 0.296\)), between cultivars and storage time (\(P = 0.281\)), cultivars and light (\(P = 0.517\)), storage time and light (\(P = 0.072\)), or among the interaction of the three factors (\(P = 0.293\)) (Table 2). Germination of fresh seeds of cultivars I, II, III, and IV in light was 19%, 20%, 18%, and 16%, respectively, but in constant darkness it was only 6%, 5%, 6%, and 4%, respectively (Fig. 1). After 3 months of incubation, seeds of cultivars I, II, III, and IV had germinated to 12%, 10%, 13%, and 11%, respectively, in light, but to only 4%, 4%, 2%, and 3%, respectively, in dark. Germination of cultivars I, II, III, and IV in light was 9%, 7%, 6%, and 9%, respectively, after 6 months of storage and 2%, 1%, 1%, and 0% respectively, after 9 months of storage. However, germination of all four cultivars had declined to 0% in light after 12

### Table 1. Comparison of the morphology and mass (mean ± SE) of seeds of the four pomegranate cultivars:

| Cultivar                  | I       | II      | III     | IV      |
|---------------------------|---------|---------|---------|---------|
| Seed length (mm) (n = 100) | 6.750 ± 0.048 | 6.799 ± 0.048 | 6.806 ± 0.047 | 6.485 ± 0.044 |
| Seed width (mm) (n = 100)  | 3.347 ± 0.033 | 3.344 ± 0.029 | 3.416 ± 0.032 | 3.523 ± 0.036 |
| Mass of 100 seeds (g) (n = 10) | 2.588 ± 0.008 | 2.508 ± 0.017 | 2.557 ± 0.010 | 2.766 ± 0.010 |

### Table 2. Three-way analysis of variance of effects of cultivar, light condition, storage time, and their interactions on germination of pomegranate seeds stored dry under laboratory conditions.

| Source              | df | Sum of squares | Mean of squares | \(F\) value | \(P\) value |

HortScience Vol. 50(6) June 2015
months of storage and to 0% in darkness after 6 months of storage (Fig. 1).

During 12 months of dry storage, seed moisture content decreased from 7.95% ± 0.14% (fresh seeds) to 5.33% ± 0.28%.

Effect of dry storage at low temperature on dormancy break. Dry storage at low temperature had a significant effect on germination percentages (P < 0.01); however, there were no significant differences among cultivars (P = 0.808). Germination in light at 25/15 °C of fresh seeds of cultivars I, II, III, and IV was 21%, 23%, 22%, and 21%, respectively, and after 2 months dry storage at 4 °C it was 31%, 34%, 36%, and 33%, respectively.

Effect of cold stratification on dormancy break. Cold stratification had a significant effect on breaking seed dormancy. After 1 month of cold stratification, germination of cultivars I, II, III, and IV was 19%, 20%, 18%, and 16%, respectively, in light at 25/15 °C, and after 3 months it had increased to 47%, 50%, 49%, and 46%, respectively (Fig. 2). Length of cold stratification period (P < 0.01) had a significant effect on germination, but cultivar did not (P = 0.688).

Effect of concentrated sulfuric acid on dormancy break. Germination percentage of seeds of the four cultivars increased with 0- to 40-min soaking time in concentrated H2SO4, but for seeds soaked for 50 min it decreased to the same level as the control (Fig. 3). Soaking time had a significant effect on germination (P < 0.01), but cultivar did not (P = 0.636).

Effect of GA3 on dormancy break. Germination percentage of all four cultivars was significantly increased by 1.0 mol·m−3 GA3, but not by 0.1 and 10 mol·m−3 GA3 (P > 0.05) (Fig. 4).

Effect of concentrated sulfuric acid followed by cold stratification on dormancy break. Soaking for 40 min in concentrated H2SO4 followed by cold stratification for 2 months was optimal for germination of fresh seeds. Germination of seeds of cultivars I, II, III, and IV was 64%, 63%, 65%, and 62%, respectively, in light at 25/15 °C. Soaking time and cold stratification time (P < 0.01) had significant effects on germination, but cultivar did not (P = 0.736) (Fig. 5).

Effect of warm stratification followed by cold stratification on dormancy break. Warm stratification followed by cold stratification had a positive effect on breaking seed dormancy. Increasing the length of the warm stratification period from 1 to 2 or 3 months significantly increased germination percentages (P < 0.01, data not shown), but the difference among germination percentages for 2 and 3 months warm-stratified seeds was not significant (P = 0.937). Data for the best combination of warm plus cold stratification for promoting germination are shown in Fig. 6. There was no effect of cultivar on germination (P = 0.822).

Discussion

The Nikolaeva–Baskin seed dormancy classification systems include five classes of dormancy: PD, morphological dormancy (MD), morphophysiological dormancy (MPD), physiological dormancy (PY), and combinational dormancy (PY + PD) (Baskin and Baskin, 2004, 2014). One-hundred percent of the pomegranate seeds incubated on moist filter paper imbibed, demonstrating that they have a water-permeable seedcoat and therefore do not have PY or PY+PD. Further, the embryo is fully developed (Martin, 1946). In which case, the seeds do not have MD or MPD. Thus, the seeds have PD. Further, since acid scarification and GA3 promoted germination, we conclude that seeds of pomegranate have the nondeep level of PD (Baskin and Baskin, 2004, 2014).
Riley (1981) reported that seeds of pomegranate cold stratified at 1 to 5 °C for 30 to 60 d germinated to 91% to 96%. In our study, seeds of pomegranate cold stratified at 4 °C for 2 months germinated to 48% to 50% (Fig. 2). However, seeds warm stratified for 1 to 3 months followed by cold stratification for 2 months germinated to 75% to 80%. Thus, warm plus cold stratification was superior to cold stratification alone in breaking seed dormancy in the four cultivars investigated in our study.

Scarification of pomegranate seeds with concentrated sulfuric acid significantly increased germination percentages in all four cultivars. However, the investigator needs to be aware of the possible danger that can result from use of this strong acid. In view of the possible danger of using concentrated sulfuric acid and the fact that seeds of pomegranate germinated to higher percentages with warm plus cold stratification than with either acid scarification, cold stratification, or scarification with concentrated H2SO4 followed by cold stratification, we recommend warm moist followed by cold moist stratification treatments for breaking dormancy in seeds of the four cultivars investigated in this study.

Fig. 5. Final germination percentages (mean ± SE) of seeds of the four pomegranate cultivars incubated at 25/15 °C in light after soaking for 0 (control), 10, 20, 30, 40, and 50 min in concentrated H2SO4, followed by cold stratification for 1 month (A) and 2 months (B). For each cultivar, different letters indicate significant differences across all treatments.

Fig. 6. Final germination percentages (mean ± SE) in light at 25/15 °C of seeds of the four pomegranate cultivars warm stratified (WS) for 1.2, and 3 months followed by cold stratification (CS) for 2 months. For each cultivar, different letters indicate significant differences across all treatments.

Rawat et al. (2010) found that wild pomegranate seeds germinated to 92% after 30 d of cold stratification at 5 °C. Acid scarification followed by cold stratification also has been found to break dormancy. Olmez et al. (2007) obtained the highest germination (84.8%) in seeds that were soaked in H2SO4 for 15 min and then cold stratified for 60 d, and Gokturk et al. (2012) obtained 60.7% germination after 30 min of soaking in H2SO4 followed by cold stratification for 45 d. In the present study, seeds soaked in H2SO4 for 40 min followed by cold stratification for 2 months germinated to 65%. Obviously, soaking in H2SO4 lowers the mechanical resistance to the seedcoat so that the embryo with low growth potential can germinate.

Fig. 6. Final germination percentages (mean ± SE) of seeds of the four pomegranate cultivars incubated at 25/15 °C in light after soaking for 0 (control), 10, 20, 30, 40, and 50 min in concentrated H2SO4, followed by cold stratification for 1 month (A) and 2 months (B). For each cultivar, different letters indicate significant differences across all treatments.
