I. INTRODUCTION

Two decades ago, Kugo and Ojima proposed a criterion for the absence of colored massless asymptoptic states in Landau gauge QCD using the Becchi-Rouet-Stora-Tyutin (BRST) symmetry \[1\]. They suggested to measure the two point function of the covariant derivative of the ghost and the commutator of the antighost and gauge field

\[
(\delta_{\mu\nu} - \frac{q_\mu q_\nu}{q^2})u^{ab}(q^2) = \frac{1}{V} \sum_{x,y} e^{-ip(x-y)} \left\langle \left( \lambda^a \dagger D_\mu \frac{1}{\partial D}[A_\nu, \lambda^b] \right)_{xy} \right\rangle.
\]

They showed that \( u^{ab}(0) = \delta^{ab} u(0) \) satisfies

\[
1 + u(0) = \frac{Z_1}{Z_3} = \frac{1}{Z_3},
\]

where \( Z_3 \) is the gluon wave function renormalization factor, \( Z_1 \) is the gluon vertex renormalization factor, and \( Z_3 \) is the ghost wave function renormalization factor, respectively. Kugo claimed that confinement is realized either by (1) \( Z_1 = 0 \) and \( Z_3 = \text{finite} \) or (2) \( Z_1/Z_3 = 0 \) but (and) \( Z_3 = 0 \). The divergence of \( Z_3 \) implies \( u(0) = -1 \) and the presence of a long-range correlation between colored sources.

As shown by Gribov \[2\], the Landau gauge is not unique and the uniqueness of the gauge field can be achieved via restriction to the fundamental modular region (FMR), i.e. the region where the norm is the absolute minimum \[3,4\]. We adopted the smearing gauge fixing \[3\] to make the configuration close to the FMR. We observed proximity of the gauge configurations with and without smearing gauge fixing, but the overlap of the Gribov region and FMR remains to be investigated.

The confinement scenario was recently reviewed in the framework of the renormalization group equation and dispersion relation \[4\]. It was shown that the gluon dressing function \( Z_A(q^2) \) defined from the gluon propagator of \( SU(n) \)

\[
D_{\mu\nu}(q) = \frac{1}{n^2-1} \sum_{x=\pm t} e^{-ikx} \left[ \left( A_\mu(x) \right)^{\dagger} A_\nu(0) \right] = (\delta_{\mu\nu} - \frac{q_\mu q_\nu}{q^2}) D_A(q^2),
\]

as \( Z_A(q^2) = q^2 D_A(q^2) \), satisfies the superconvergence relation, and the gluon dressing function at zero momentum does not necessarily vanish as Gribov and Zwanziger conjectured, but it could be finite. A systematic study of lattice data indeed establishes the infrared finiteness of the gluon propagator \[5\].

The ghost propagator is defined as the Fourier transform of an expectation value of the inverse Faddeev-Popov (FP) operator \( \mathcal{M} \)

\[
D_G^{ab}(x,y) = \langle \text{tr}(\lambda^a x(\mathcal{M}[U])^{-1}(\lambda^b y)) \rangle,
\]

where the overline \( \langle \cdots \rangle \) denotes average over samples \( U \). The infrared behavior of the ghost propagator in the renormalization group approach depends on the gauge,
and whether it satisfies the superconvergence relation is not clear. In maximal abelian
gauge, it is conjectured that the off-diagonal gluon and off-diagonal ghost satisfy the superconvergence relation, but the diagonal ghost does not, and it is the source of the long-range correlation.

We remark that Nishijima proposed a sufficient condition for the confinement as $Z_3 = 0$, based on the convergence of the spectral function $\xi$. The non-perturbative color confinement mechanism was studied with the Dyson-Schwinger approach and lattice simulations. We produced $SU(3)$ gauge configurations by using the heat-bath method and performed gauge fixing. We analyzed lattice Landau gauge configurations of $\beta = 6.0, 16^4, 24^4, 32^4$ and $\beta = 6.4, 32^4, 48^4$ produced at KEK. Progress reports are presented in and an extensive outlook are presented in sec. V. Some details of our method of calculating the FP inverse operator are given in the appendix.

II. METHOD OF ANALYSIS

In the infrared region, the QCD perturbation series does not converge and truncation of the renormalization group equation and resummation of the series to evaluate the renormalon effect was proposed. On the other hand, the possibility of the presence of an infrared fixed point was discussed and methods to bridge infrared and ultraviolet regions via the renormalization group equation were proposed. The method was recently applied to an analysis of lattice data and succeeded in explaining qualitatively the data. We briefly review the method.

A. PMS and the effective charge method

In the PMS method, the $n$th-order approximation to the physical quantity $R$ is expressed by the corresponding series of coupling constant $h^{(n)}$ which is defined as a solution of

$$\beta_0 \log \frac{\mu^2}{\Lambda^2} = \frac{1}{h} + \frac{\beta_1}{\beta_0} \log(\beta_0 h)$$

$$+ \int_0^h dx \left\{ \frac{1}{x^2} - \frac{\beta_1}{\beta_0 x} - \frac{\beta_0}{\beta_0 x^2 + \beta_0 x^3 + \cdots + \beta_n x^{n+2}} \right\},$$

where the scheme-independent constant and logarithmic term are separated.

When $R$ is the QCD running coupling from the triple gluon vertex from up to three-loop diagrams in the modified minimal subtraction (MS) scheme, one sets the scale $\mu^2$ equal to the external scale $g^2$ and expresses

$$R^n = h^{(n)}(1 + A_1 h^{(n)} + A_2 h^{(n)2} + \cdots + A_n h^{(n)n}),$$

where in the case of $n = 3, A_1 = 70/3, A_2 = \frac{516217}{576} - \frac{153}{4}, A_3 = \frac{304676635}{6912} - \frac{299961}{64} - \frac{81825}{64}.$$ When one defines $y_{MS}(q)$ as a solution of

$$1/y_{MS}(q) = \beta_0 \log(q/\Lambda_{MS}^2) - \frac{\beta_1}{\beta_0} \log(\beta_0 y_{MS}(q))$$

and expresses the solution of Eq. (5)

$$h(q) = \frac{1}{2}(\beta_3/\beta_0 - (\beta_1/\beta_0)^3) + \cdots,$$

and

$$y_{MS}(q) \{ 1 + y_{MS}(q)^2 (\beta_2/\beta_0 - (\beta_1/\beta_0)^2) + \cdots \}.$$
where $\beta_0 = 11, \beta_1 = 102, \bar{\beta}_2 = \frac{2857}{2}, \bar{\beta}_3 = \frac{149753}{6}$, and 35643, we can calculate $\mathcal{R}$ via eq. (16).

The parameter $\tilde{\alpha}(q)$ can be expressed as $y$ defined as a solution of

$$\beta_0 \log \frac{\mu^2}{\Lambda^2} = \frac{1}{y} + \beta_1 \frac{1}{\beta_0} \log(\beta_0 y)$$

and the function

$$k(q^2, y) = \frac{1}{y} + \beta_1 \frac{1}{\beta_0} \log(\beta_0 y) - \beta_0 \log(q^2/\Lambda^2_{\overline{\text{MS}}}).$$

In [27] the parameter $y$ is fixed via minimization of $(\mathcal{R}^n(y) - \mathcal{R}^1(y))/\mathcal{R}^1(y)$ for each $q^2$. There are subtle problems in fixing $y$ of PMS in the low-energy region. We leave the fitting of the low energy region for the future and we fix $y$ at $\mu = 1.97$ GeV by solving

$$1/y = \beta_0 \log(\mu/\Lambda)^2 - \beta_1 \frac{1}{\beta_0} \log(\beta_0 y).$$

The choice of $\mu = 1.97$ GeV corresponds to the inverse lattice unit $1/a$ of $\beta = 6.0$ and chosen by [11] as the factorization scale of the effective charge method. When $\Lambda = \Lambda_{\overline{\text{MS}}} = 0.237$ GeV we find the solution $y = 0.01594$, and we call this method of choosing $y$ at a specific $\mu$ and define $\alpha_s$ from ghost-ghost-gluon coupling, the MOM scheme.

B. Contour-improved perturbation series

Exact solution of the two-loop renormalization group equation for $x$ with variable $t = \log q^2/\Lambda^2$

$$\beta(x) = \frac{dx}{dt} = -\frac{b}{2} t^2 (1 + cx),$$

is

$$\frac{b}{2} \log(q^2/\Lambda^2) = \frac{1}{x} - c \log(1/x + c).$$

The solution $x$ can be expressed as $x(q^2) = -\frac{1}{1 + W(z)}$, where $W(z)$ is the Lambert W function which satisfies $W(z)e^{W(z)} = z$. We apply the dispersion relation and consider contributions on a cut of negative real axis in the space of $q^2$, i.e. take $q$ pure imaginary. In order to be consistent with the MS scheme, the variable $z$ is defined as

$$z = -e^{-1-1-it/2c} = -\frac{1}{e^{\frac{1}{\Lambda_{\overline{\text{MS}}}}}} = -Z(q^2)e^{iK\pi},$$

where $t = \log(q^2/\Lambda^2_{\overline{\text{MS}}}^2), \Lambda_{\overline{\text{MS}}} = (2c/b) - e/c\Lambda_{\overline{\text{MS}}}, K = -b/2c$ [28] and the function $Z(q^2)$ is expressed in a series

$$\mathcal{R}(q^2) = \mathcal{B}_1(q^2) + \sum_{n=1}^{\infty} A_n \mathcal{B}_n(q^2)$$

$$\mathcal{B}_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{-1}{c(1+W(Z(q^2)e^{iK\pi}))^n} d\theta. \ (16)$$

III. LATTICE DATA

A. Gluon propagator

The gluon propagator on the lattice was measured by using cylindrical cut method [12], i.e., choosing momenta close to the diagonal direction. When the difference of their lattice constant $\alpha^{-1} = 1.885$ GeV in $\beta = 6.0, 32^3 \times 64$ and our $\alpha^{-1} = 1.97$ GeV, $32^4$ is taken into account, the data are consistent with [12] (see Fig. 1).

The effective coupling $y$ of the MOM scheme is calculated from

$$1/y = \beta_0 \log(\mu/\Lambda^2) - \beta_1 \frac{1}{\beta_0} \log(\beta_0 y).$$

for $\mu = 1.97$ GeV and $\Lambda^2 = \Lambda_{\overline{\text{MS}}}^2 = 25085/37752$ [28] obtained from the three-gluon vertex in Landau gauge perturbation theory. The relevant solution of eq. (17) is $y = 0.02227$.

The gluon dressing function is defined as $Z_A(q^2) = q^2 D_A(q^2)$. Its inverse $Z^{-1}$ is expressed in the two-loop perturbation series as [28]

$$Z^{-1}(q^2, y) = \lambda_z^{-1} h^{(2)}(2) - \frac{25085}{2904} (1 - \frac{25085}{2904}) (1 - \frac{1}{25085})\lambda_z^{(2)}$$

$$\left( -\frac{41245993}{1874048} - \frac{9747}{352} \right) (\lambda_z^{(2)})^{(17)},$$

where $\lambda_z$ is a fitting parameter (see Fig. 2).

As shown in Fig. 1 and Fig. 3 the gluon propagators of $24^4, 32^4$ and $48^4$ as a function of the physical momentum agree quite well with one another and they can be fitted by

$$D_A(q^2) = \frac{Z(q^2, y)|_{y=0.02227}}{q^2} = \left(\frac{Z_A(q^2)}{q^2}\right),$$

in the $q > 0.8$ GeV region. At zero momentum, $D_A(0)$ decreases as the lattice size becomes larger.

The gluon dressing function in the MOM scheme with $y = 0.02227$ fits the lattice data for $q > 0.8$ GeV, but there appears a discontinuity at $z \simeq 0.174$ and $z = 1/e$. We note that the $q$ dependence of $Z(q^2, y)$ in $z < 0.17$ is similar to $1/W_0(0.17 - z)$, that in $0.17 < z < 1/e$ is similar to $1/W_0(0.17 - z)$, and that in $z > 1/e$ is similar to $1/W_0(z-1/e)$.
FIG. 1: The gluon propagator as the function of the momentum $q$(GeV). $\beta = 6.0$, 24\(^4\) (triangles), 32\(^4\) (diamonds) and $\beta = 6.4$, 48\(^4\) (stars) in log $U$ definition.

FIG. 2: The dressing function $\lambda Z(q^2, y)$ as a function of the variable $z$ for a fixed $y = 0.02227$. The branches of the Lambert $W$ function $1/W_0(0.17 - z)$, $\text{Re}[W_{-1}(0.17 - z) + W_{-1}(z - e^{-1})]$, and $1/W_0(z - e^{-1})$ are shown as dotted lines.

FIG. 3: The gluon dressing function as the function of the momentum $q$(GeV). $\beta = 6.0$, 24\(^4\) (triangles), 32\(^4\) (diamonds) and $\beta = 6.4$, 48\(^4\) (stars) in the log $U$ version. The fitted line is that of the MOM scheme.

B. Ghost propagator

The ghost dressing function is defined by the ghost propagator as $G^{ab}(q^2) = q^2 D_G^{ab}(q^2)$. In the MOM scheme, we fix the scale by choosing $y$ as a solution of

$$1/y = \beta_0 \log(\mu/\Lambda_{gh})^2 - \beta_1/\beta_0 \log(\beta_0 y).$$

(20)

For $\mu = 1.97$ GeV and $\Lambda_{gh} = \Lambda_{\overline{MS}}^{1757/2904}$ obtained from two-loop Landau gauge perturbation theory, we find as a relevant solution $y = 0.02142$.

The ghost dressing function is

$$Z_g^{-1}(q^2, y) = \lambda_g h(2)^{-9/44}\left[1 + h(2)^2 (-5271/1936) + \frac{615512003}{7496192} \zeta_3 + \cdots\right] + \cdots,$$

(21)

where $\lambda_g$ is a fitting parameter.

In Fig. 4, the 24\(^4\), 32\(^4\), and 48\(^4\) lattice data are compared with

$$D_G(q^2) = -\frac{Z_g(q^2, y)|_{y=0.02142}}{q^2} = \frac{G(q^2)}{q^2}.$$

(22)

FIG. 4: The ghost propagator as the function of the momentum $q$(GeV). $\beta = 6.0$, 24\(^4\), 32\(^4\) and $\beta = 6.4$, 48\(^4\) in the log $U$ version. The fitted line is that of the MOM scheme. $Z_g(q^2, y)$ is singular at $\tilde{\Lambda}_{\overline{MS}} \simeq 0.25$ GeV which should be washed away by the nonperturbative effects.

We observe that the agreement is good for $q > 0.5$ GeV and better than the result of the PMS method. The ghost propagators were calculated by the perturbative method and the straightforward and preconditioned CG methods. We found that the two CG methods are consistent and give better accuracy than the perturbative method in SU(2), and give correct result in the lowest momentum point of SU(3) 48\(^4\) lattice. With the lowest momentum point of the 48\(^4\) lattice calculated with the CG method, the whole data can be fitted by Eq. (22).
C. QCD running coupling

We measured the running coupling from the product of the gluon dressing function and the ghost dressing function squared [4].

$$\alpha_s(q^2) = \frac{g_0^2}{4\pi} Z_A(q^2) G(q^2)^2 \simeq (qa)^{-2(\alpha_D + 2\alpha_G)}.$$ (23)

The lattice size dependences of the exponents $\alpha_D$ and $\alpha_G$ are summarized in Table I.

| $\beta$ | L | $\alpha_D$ | $\alpha_D'$ | $\alpha_G$ | $\alpha_D + 2\alpha_G$ |
|--------|---|-----------|-----------|---------|----------------|
| 6.0    | 32 | -0.375    | 0.302     | 0.174   | -0.03(10)      |
| 6.4    | 48 | -0.273    | 0.288     | 0.193   | 0.11(10)       |

The effective running coupling in the $\overline{\text{MS}}$ scheme is expressed by the series of coupling constants $h^{(n)}$ as eq. 23 [27, 28]. The result of the MOM scheme using $y = 0.01594$ is shown by the solid line in Fig. 5. The lattice data of 24$^4$, 32$^4$ and 48$^4$ and the MOM scheme agree in 0.5GeV $< q < 2$GeV, but the fit is slightly overestimated at $q > 2$ GeV.

Since the $A_3$ term is not known and there are cancellations between successive terms, we fit the data by inclusion of half of the $A_2$ term. The result is shown by the dotted line in Fig. 6.

D. Kugo-Ojima parameter

Our lattice data of (1) the Kugo-Ojima parameter $c = -u(0)$, (2) the trace of the gauge field divided by the dimension $e/d$, and (3) the deviation parameter $h$ from the horizon condition [13] are summarized in Table II.

We observe that the Kugo-Ojima parameter of the $U$ linear definition remains smaller than that of log $U$. The similar difference exists in the ghost propagator in the infrared region.

| $\beta$ | L | $c_1$ | $c_1/d$ | $h_1$ | $c_2$ | $c_2/d$ | $h_2$ |
|--------|---|------|--------|------|------|--------|------|
| 6.0    | 16 | 0.576(79) | 0.860(1) | -0.28 | 0.628(94) | 0.943(1) | -0.32 |
| 6.0    | 24 | 0.695(63) | 0.861(1) | -0.17 | 0.774(76) | 0.944(1) | -0.17 |
| 6.0    | 32 | 0.706(39) | 0.862(1) | -0.15 | 0.777(46) | 0.944(1) | -0.16 |
| 6.4    | 32 | 0.650(39) | 0.883(1) | -0.23 | 0.700(42) | 0.953(1) | -0.25 |
| 6.4    | 48 | 0.793(61) | 0.954(1) | -0.16 |
We plot in Fig. 7 the value $c$ as a function of $\log Z(\mu^2)$ of $\beta = 6.0, 16^4$, and $24^4$ in $\log U$ and $U$ linear definitions and $\beta = 6.4, 32^4$ and $48^4$ in the $\log U$ definition. The value $c$ of $\beta = 6.0, 32^4$ is almost the same as $24^4$. The value increases as the lattice size increases from $16^4$ to $24^4$ and the extrapolation of the two definitions to those of a large lattice where $c$ in $\log U$ and $U$ linear seem to cross at $c \sim 1$. The linear extrapolation as the function of $\log Z(\mu^2)$ is based on the factorizability

$$Z_3(\mu^2, \Lambda_{\text{MOM}}) = Z_R(\mu^2)/Z_b(\Lambda_{\text{MOM}})$$

(25)

when $\mu \sim 1.97$ GeV, which allows us to express

$$Z_3(\mu^2, \Lambda_{\text{MOM}}) = Z_3(\mu^2, \Lambda_{\text{MS}}) \times (Z_b^{-1}(\Lambda_{\text{MOM}})/Z_b^{-1}(\Lambda_{\text{MS}}))$$

(26)

The difference of the speed of $Z_b(\Lambda_{\text{MOM}})$ to its continuum limit in the $U$ linear and $\log U$ definitions will appear as a difference of the slope. However, the increase of $c$ from $24^4$ to $32^4$ is small. The Kugo-Ojima parameter $c$ of $\beta = 6.4, 48^4$ lattice calculated in the CG method is $0.793(61)$, which is consistent to the result of the $\log U$ definition of $\beta = 6.0, 24^4$, and $32^4$ lattice data.

### IV. SU(2) LATTICE DATA

In the numerical simulation of the SU(2) Yang-Mills field, we took the $U$ linear type gauge field and simulated $\beta = 2.2$ and $16^4$ lattices. We took 67 samples taken after 18 000 thermalization sweeps and up to 84 000 sweeps with intervals of 1000 sweeps [16]. To each sample, we performed parallel tempering gauge fixing (PT) and direct gauge fixing by the overrelaxation method (first copy). We define the scale by the relation $1/a = 0.938$ GeV and compare our data with those of [34, 35] and [36].

#### A. Gluon propagator

The gluon propagator is shown in Fig. 8. We observe that above 1 GeV our data agree with [34], but in the infrared region our data have an enhancement. Suppression at 0 momentum is consistent with the data of [33].

#### B. Ghost propagator

The color diagonal component of the ghost propagator calculated in PT is about 6% less singular than that of first copy (Fig. 9). We performed the calculation of the FP inverse operator by using the CG method, since the matrix is symmetric positive definite. Our data in the infrared are less singular than that of [34]. Although there are difference in the gauge fixing method (PT versus simulated annealing), we do not understand the origin of the difference.

![Gluon propagator](image1)

FIG. 7: The Kugo-Ojima parameter $c$ as a function of $\log Z(1.97\text{GeV})$. $\beta = 6.4, 32^4, 48^4$ in $\log U$ (stars), $\beta = 6.0, 16^4$ and $24^4$ in $\log U$ (triangles) and $U$ linear (diamonds) versions.

![Gluon propagator](image2)

FIG. 8: The gluon propagator $D_A(q)$ as a function of the momentum $q(\text{GeV})$ of PT samples.

![Gluon propagator](image3)

FIG. 9: The color diagonal ghost dressing function $D_G(q^2)$ as a function of the momentum squared $q^2(\text{GeV}^2)$. The first copies (diamonds) are more singular than PT (triangles).
In the maximal abelian (MA) gauge, color symmetry is spontaneously broken by the ghost condensation \[37, 38\]. In the Landau gauge, there is no background field as in the MA gauge, but the structure of the color off-diagonal ghost propagator has not been known. In order to investigate this problem, we measured color off-diagonal symmetric and antisymmetric \((\epsilon_{abc}D_G^{ab}(q, q))\) matrix elements, where \(D_G^{ab}(q, q)\) is the ghost propagator with color indices \(a\) and \(b\). We observed that the color off-diagonal antisymmetric part is consistent with zero pointwise as expected from the theoretical observation and that the color off-diagonal symmetric part multiplied by \(q^4\) is consistent with zero over the ensemble average, but its standard deviation is almost constant in the whole momentum region. The fluctuation can be parametrized as \(\sigma/q^4\) with \(\sigma = 0.0176(28)\) \(\text{GeV}^2\), in the normalization \(\tau^2 = 1\). We observed the same qualitative features in the SU(3) 48\(^4\) lattice, but \(\sigma\) is about 1/9 of the SU(2) 16\(^4\) lattice, i.e., the fluctuation is statistical.

C. QCD running coupling

The result of the running is shown in Fig. 10. As a result of the difference in the ghost propagator, the running coupling is about 1/3 of \([29, 44, 45]\). We observe suppression near 0 momentum.

![Fig. 10: The running coupling \(\alpha_s(q)\) as a function of the momentum \(q(\text{GeV})\) of PT samples.](image)

D. Kugo-Ojima parameter

The Kugo-Ojima parameter \(c\) of the PT samples was 0.690(52) and that of the first copy was 0.722(68). This difference is qualitatively the same as that of the ghost dressing function at 0 momentum.

V. CONCLUSION AND OUTLOOK

There are two aspects of color confinement: i.e., (1) the presence of long-range correlation between colored sources and (2) the absence of massless gluon poles. The Kugo-Ojima criterion is a sufficient condition for the two aspects, but the lattice data do not verify that these criteria are satisfied.

A new method of FMR gauge fixing in SU(2) is reported in [16]. We observe that the gluon propagator is suppressed at zero momentum in SU(2), i.e., the exponent \(\alpha_D < -0.5\), in contrast to the SU(3) case where \(\alpha_D > -0.5\). In the simulation of SU(2), we observed differences in the Kugo-Ojima parameter of the configuration in the FMR and of copies randomly produced in the Gribov region. The Gribov copy affects the Kugo-Ojima parameter, and in the ghost propagator in the infrared region, the difference is about 4\%. Color SU(3) contains I, U and V SU(2) spin components, and we expect that the Gribov ambiguity is the same order.

In the lattice data, the singularity of the ghost propagator is stronger than the tree level and that of the gluon propagator is weaker than the tree level. The dependence on the \(U\) linear or log \(U\) definition of the gauge field is small in the gluon propagator consistent with [39], but not negligible in the FP inverse operator.

We aimed at detecting in the lattice dynamics a signal of the Kugo-Ojima confinement criterion derived in the continuum theory, formulated with use of the FP Lagrangian and BRST symmetry. We also noted that Zwanziger’s horizon condition, based on the lattice formulation, coincides with the Kugo-Ojima criterion [3, 13]. However, our present data are not satisfactory to prove or disprove the confinement criterion. The color off-diagonal antisymmetric part of the ghost propagator [37, 40] vanishes in the Landau gauge, but the off-diagonal symmetric part has fluctuations proportional to \((qa)^{-4}\).

Although there are problems in fixing \(y\) of the PMS in the low-energy region, an extension of the effective charge method is a possible solution. In an extension of the solution of the two-loop renormalization group equation expressed by the Lambert-\(W\) function, a solution of Padé approximant of the three-loop renormalization group equation was shown [11] and numerical calculation was done for \(N_f \geq 3\) [42]. In the analytical perturbation theory approach in one loop, one predicts [43] a non-perturbative infrared fixed point of \[\frac{\alpha_s(0)}{4\pi} = \frac{1}{\beta_0} = \frac{1}{11 - 2/3N_f}\]. Extension to the two-loops is discussed in [11]. For \(N_f = 0\), one needs continuation. There is a conjecture, in combination with the conformal relation, that continuation from \(N_f\) in the conformal window (4 \(\leq N_f \leq 6\)) to \(N_f = 0\) would be possible [29, 44, 45].

We remark that the Orsay group analyzed QCD running coupling in the Landau gauge from three gluon vertex. They separate the momentum space into \(q < \)
We observed a specific color symmetry violation pattern, and in the case of SU(3) relatively large color off-diagonal matrix elements suppressed the color diagonal matrix element. For a cross-check of the perturbative method, we adopted the straightforward conjugate gradient method and the preconditioned conjugate gradient method in which the truncated perturbation series is used for the preconditioning.

2. Preconditioned conjugate gradient method

We define $M = -\partial^2 (I - M)$ and define the truncated $M^{-1}$ which is used in the perturbative method as $B^{-1} = (I + M + \cdots + M^{m-1})(-\Delta)^{-1}$. First we choose $x^0$ and define $r^0 = b - Mx^0$. Using the multigrid Poisson solver we calculate the perturbation series

$$r^{k+1} = \alpha_k r^k + \alpha_k M p^k. \quad (A.5)$$

We check the norm of $r^{k+1}$, and if it is not small, we calculate the perturbation series $\tilde{r}^{k+1} = B^{-1}r^{k+1}$ as before. We define

$$\beta_k = (\tilde{r}^{k+1}, r^{k+1})/(\tilde{r}^{k}, r^{k}), \quad (A.6)$$

and go back to the beginning of the iteration cycle. By choosing a sufficiently large number of $m$, the convergence occurs after a few iteration cycles.

The preconditioned method makes the $l_2$ norm convergence faster than the straightforward conjugate gradient method, but its maximum norm is larger than that of straightforward method. The solution agrees with the straightforward conjugate gradient method within errors in the whole momentum region, but disagrees with the perturbative method in the lowest momentum point of $\beta = 6.4$, SU(3) $48^4$ lattice.

Acknowledgments

We are grateful to Daniel Zwanziger for enlightening discussions. S.F. thanks Kei-Ichi Kondo, Stanley Brodsky, Karel van Acoleyen, David Dudal and Kurt Langfeld for valuable information.

APPENDIX: THE NUMERICAL CALCULATION OF THE FADDEEV-POPOV INVERSE

In this appendix we briefly explain the numerical method of calculating the Faddeev-Popov inverse.

1. Perturbative method

The ghost propagator, which is the Fourier transform of an expectation value of the inverse Faddeev-Popov operator $M = -\partial^2 (I - M)$,

$$D_G^b(x, y) = \langle \{M[U]\}^{-1} | \lambda^b | y \rangle, \quad (A.1)$$

where the outmost $\langle \cdots \rangle$ denotes average over samples $U$, is evaluated as follows. We take the plane wave for the source $b^{[i]} = \lambda^b e^{iq}x$ and get the solution $-\Delta \phi^{[i]} = b^{[i]}$. Here $\phi^{[i]} = (-\Delta)^{-1} b^{[i]}$. We calculate iteratively $\phi^{[i+1]} = M\phi^{[i]}(x)(i = 1, \cdots, k - 1)$. The iteration was continued until the maximum norm $\max_x |\phi^{[k]}(x)|/\max_x |\sum_{i=1}^{k-1} \phi^{[i]}(x)| < 0.001 \sim 0.01$. The number of iterations $k$ is of the order of 60, in SU(2), 16$^4$ lattice, and of the order of 100 in SU(3). We measure also the $l_2$ norm $\|\phi^{[k]}(x)\|/\|\phi^{[1]}(x)\|$.

We define $\Phi^b(x) = \sum_{i=1}^{k} \phi^{[i]}(x)$ and evaluate $\langle \lambda^b e^{iq}x, \Phi^a(x) \rangle$ as the ghost propagator from color b to color a.

In the low-momentum region of SU(2) we observed a specific color symmetry violation pattern, and in the case of SU(3) relatively large color off-diagonal matrix elements suppressed the color diagonal matrix element.
