Citation: Dybowski B, Bres-Niewada E, Rzeszutko M, et al. Risk factors for infectious complications after retrograde intrarenal surgery – a systematic review and narrative synthesis. Cent European J Urol. 2021; 74: 437-445.

INTRODUCTION

With the development of laser and endoscopic technology, retrograde intrarenal surgery (RIRS) is gaining new indications, and the number of procedures is constantly growing [1]. However, RIRS is associated with complications, and infectious complications are among the most common. Infectious complications result from the combination of increased pressure in the collecting system and the presence of bacteria in the urinary tract. The identification of independent predictors should reduce the risk of infectious complications. To date, most studies on the risks associated with a ureteroscopy (URS) have analyzed complications after ureteral stone surgeries or combined ureteral and intrarenal lithotripsy [2, 3]. However, intrarenal and intrarenal lithotripsy have different characteristics. Thus, this
study aimed to summarize the available data from multivariate analyses on risk factors for infectious complications after RIRS. We divided the factors identified into (a) well-established, independent predictors of infection, (b) potential independent predictors that require complementary studies, and (c) factors that, based on the vast majority of evidence, are irrelevant or dependent on other, truly independent factors.

**MATERIAL AND METHODS**

This systematic review was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) statement [4]. We created a Population, Intervention, Comparison and Outcomes review protocol, which was registered in the PROSPERO registry (ID: CRD42021249976). The literature search was restricted to 2014–2021. We did not restrict the language. We searched Medline, Scopus, and the Cochrane Library with the following search strategy: (septic OR infection OR sepsis OR infectious OR SIRS OR systemic inflammatory OR urosepsis) AND (RIRS OR retrograde OR intrarenal OR ‘flexible ureteroscopy’). We searched Google Scholar with the following string: (‘flexible ureteroscopy’ OR ‘retrograde intrarenal’) (fever OR infection OR inflammatory) (factors OR predictors). We also searched relevant individual urologic journals. We scrutinized references and citations of each relevant study to extend the search range. The search was completed on April 21st, 2021.

Two reviewers extracted all data and discussed any differences. Patient demographics, the surgery technique, stone characteristics, the type and incidence of infectious complications, and the results of univariate and multivariate analyses of risk factors were recorded with Microsoft Excel 2019. Each relevant study was assessed for quality by carefully evaluating the published results, the compliance of results with our objectives, and the study methodology. We evaluated non-randomized studies with the methodological index for non-randomized studies (MINORS) questionnaire [5]. Due to the heterogeneous nature of the data available in the source publications, the various measures of variation, and the variable ranges of the parameters studied, we decided to perform a narrative synthesis, instead of a meta-analysis [6].

**RESULTS**

**Characteristics of the included studies**

We initially identified 2330 articles and processed them according to the PRISMA guidelines (Figure 1). Seventeen full-text English language articles were included in this systematic review (Table 1) [7–23]. The studies were published in 2015–2021, most (10/17) in the last 30 months (January 2019 to May 2021). Two studies [9, 16] were conducted prospectively. All but one [9] study described a single-center experience. We included a total of 7662 RIRS procedures.

Study quality was assessed with the MINORS questionnaire, which included eight items, with a maximum score of 16 (Table 2) [5]. All studies clearly stated the aims and adequately defined the endpoints. No study mentioned using an intention-to-treat analysis, but we did not deduct points for this item, due to the retrospective nature of most studies. Although no studies described blinded evaluations of the study endpoints, we assumed that all endpoints were based on objective measurements performed by a staff nurse that was not involved in the research; conse-
### Table 1. Details of the studies included in the systematic review. All risk factors of post-RIRS infectious complications identified in univariate analyses are listed. Factors found significant in multivariate analyses are bolded.

| Study                  | Sample size | Technique variations | Mean operative time (min.) | Type/grade of infectious complications and morbidity | Risk factors                                                                 |

| Baboudjian et al. [18], 2020 | 604         | Irrigation with pressure-controlling pump (60–70 cmH₂O) | 61                          | Fever – 6.7%                                      | Operative time, UTI history, (+) urine culture >1 species, Gender (female), Stone size, History of antibiotics |
| Zhang et al. [19], 2020 | 602         | srURS Irrigation unknown | 62                          | Fever – 10.6%, SIRS – 7.1%                         | Operative time, Stone >20 mm, (+) urine culture                             |
| Peng et al. [20], 2020 | 1493        | Syringe manual irrigation | 30                          | Fever – 4.9%, Sepsis – 0.5%, Septic shock – 0.3%   | Gender, Urine test (+), Infection stone, Postoperative neutrophil ratio >75% |
quently, all studies received 2 points for this item. Two studies received 2 points each for their prospective study design. One point was deducted for lack of exclusion criteria in four studies. Two points were given when the specified follow-up exceeded the hospitalization time, and only one point was given when the follow-up was restricted to the hospital stay. In three studies, one point was deducted for overly high exclusion rates or overly restrictive exclusion criteria. No study had estimated the statistical power of the study or the appropriate sample size. However, one point was given to studies that included more than 400 patients, and a second point was given to studies that provided the odds ratios and 95% confidence intervals for independent prognostic factors. Four publications scored 14 or 15 points [9, 13, 16, 18] and four studies scored 13 points [10, 11, 14, 20]. However, articles that scored high were not distinctively different from those that scored low in terms of factors analyzed and results.

RIRS technique
All studies that described their technique used perioperative antibiotic prophylaxis, ureteral access sheaths (UAS), postoperative JJ stenting, and holmium laser for intrarenal lithotripsy (the power and other settings were typically not provided). Variations in the RIRS technique (Table 1) included:
- prestenting (routinely used in four centers);

MINORS – methodological index for non-randomized studies
Endpoints and risk factors

The studies used one of two primary endpoints: systemic inflammatory response syndrome (SIRS, in three studies [7, 17, 19]) and fever (in 14 studies). Despite differences in endpoint definitions, the incidence rates were similar: fever was observed in 2.8–7.5% of patients (mean 7.1%), and the mean incidence of SIRS was 7.9%. No study described the effects of surgeons’ experience on the incidence of infectious complications: the rates of postoperative infections were similar between large cohorts (>400 patients) and small cohorts (≤400; p = 0.12, 

- initial semi-rigid ureteroscopy (srURS); six centers routinely used srURS; one center routinely used both prestoneting and srURS; technical details were given in 9 of 14 studies, and ureteral dilatation was always obtained with either prestoneting or srURS;
- the UAS diameter (not specified by most authors);
- the ureteroscope type and diameter;
- the irrigation type and pressure (not specified in eight studies, gravity used in six studies, manually applied with a syringe in one study, and pressure-controlling pump in two studies); the effect of the irrigation type was not verified.

Table 3. Risk factors for infectious complications after retrograde intrarenal surgery and their significance in univariate and multivariate analysis

— insignificant; + – significant in univariate analysis; ! – significant in multivariate analysis; MV+ – number of studies showing significance in multivariate analysis; UV+ – number of studies showing significance in univariate analysis
U-Mann-Whitney test). No study found a correlation between the mean duration of the RIRS procedure and the rate of infectious complications (correlation coefficient \( r_{xy} = 0.02 \)). All investigators performed logistic regression analyses to identify preoperative parameters associated with infectious complications. The choice of examined factors varied (Table 3), but some parameters were examined in all or most studies, including: sex, age, body mass index, diabetes, presence of hydronephrosis, stone location, preoperative bacteriuria, stone size, and operative time. Four to 10 centers examined the following: prestenenting, anatomical anomaly of the kidney, a history of urinary tract infection, stone composition, UAS caliber, a history of stone surgery, and a preoperative urinalysis. One to three studies examined comorbidity scores, preoperative C-reactive protein, a stone or collecting system urine culture, the irrigation rate, and antibiotic therapy.

Only four studies found no relationship between the operative time and infectious complications. Of those, three did not find any well-known predictors, [9, 15, 23] and one reported on rarely investigated factors, such as the irrigation rate, stone composition, and UAS caliber [7]. The other 13 studies found that the operative time was related to postoperative infections. Most studies analyzed time as a continuous variable, but four used thresholds. Among these, significant relationships were found at thresholds of 70 min [10], 60 min [16], and 30 min [21]; but the relationship was insignificant with a threshold of 120 min [7]. Most studies found that stone size and preoperative urine culture were significantly related to postoperative infections, although most performed univariate, not multivariate analyses. Some studies found that postoperative infections were significantly related to the stone composition (infected stone), abnormal urinalysis, or recent antibiotic use abnormalities, but not the urine culture. Only three studies [9, 14, 16] showed no correlation between a fever/SIRS and an abnormal urine culture, urinalysis, the presence of infection or struvite stone, or antibiotic use. In two studies [14, 16], highly restrictive criteria were used to exclude patients with an infection or bacteriuria, and none of the above parameters were included in the analysis. However, the results of those studies may be important for patients without bacteriuria and prolonged surgery times. Three studies highlighted the importance of comorbidities, although they reported postoperative infection rates as low as <8%. Jian et al. and Peng et al. [20, 21] showed even better statistics, but it was difficult to find a single common element between these studies, apart from the country of origin and the large numbers of patients included. They were both recent studies that showed that the preoperative urinalysis was more important than a urine culture as an independent predictor of complications. The UAS caliber, stone composition (one author proposed an intraoperative analysis of stone composition), irrigation rate, and comorbidities are among potentially influencing factors that have been insufficiently studied in the context of multivariate analyses. Most authors included age, gender, diabetes mellitus, body mass, hydronephrosis, and stone location in their analyses, but the vast majority of studies found insignificant relationships to infectious complications of RIRS.

The results of two studies were considered debatable. In the only multicenter study [9], no prognostic factor was significantly associated with infectious complications in the multivariate analysis, but the univariate analysis showed an association with comorbidities. In the study by Mi et al. some differences seem unlikely to be significant; e.g., the surgery times differed by one minute and the stone sizes differed by a few millimeters between groups. Nevertheless, we did not exclude these works from the analysis. Our choice of a narrative synthesis and our reliance on the results shown in Table 3 ensured that the results of these works did not affect the conclusions of the entire analysis.

**DISCUSSION**

This systematic review was the first to specifically focus on infectious complications after a RIRS. However, a number of review articles have de-
scribed infectious complications after an unspecified ureteroscopy. Moreover, in the present study, most original reports were published in the last 2.5 years, and thus, they were not included in previous systematic reviews. Unlike reviews on the semi-rigid ureteroscopy, we did not perform a meta-analysis, because this method would significantly limit the scope of the evidence, and it would have excluded recently emerging factors that are supported by little evidence. Indeed, the latest research has revealed several new factors that were not studied previously.

We estimated that the average incidence of fever after RIRS was about 7%, which was higher than that found in studies on semi-rigid ureteroscope procedures (2–3.8%) [3, 24]. This finding confirmed the notion that patients undergoing RIRS might be at higher risk of infectious complications than patients undergoing semi-rigid ureteroscopy. Thus, these two procedures should be analyzed separately. This study could not confirm the value of many factors previously recognized as important in ureteroscopy; e.g., age, sex, body mass, diabetes, or hydronephrosis. Additionally, some variables, such as the JJ stent dwell time or lower urinary tract neurogenic dysfunction, were not analyzed in any of the studies we examined.

We found that, operative time was a risk factor for post-RIRS infections. It was included in all 17 articles, and it was considered significant by the vast majority of authors. Based on studies by Alezra et al., Ozgor et al., and other specific analyses, an operating time over 60 min is currently considered to increase the risk of infectious complications. Although stone size seems to affect the operating time in fact it was not found an independent predictor by majority of researchers. It is because the time is rather determined by the surgeon’s decision to halt RIRS, the individual skills of the operator, and the composition of the stone. Most of the analyzed studies (13 of 17) revealed that, apart from the operating time, various factors related to presurgical urinary tract infections were independent predictors. These factors included a positive urine culture, stone composition, and the use of antibiotics before surgery. In the most recent studies, an abnormal presurgical urinalysis was also identified as an independent predictor of infectious complications [20, 23].

The intrarenal pressure applied during surgery can allow bacteria to penetrate the collecting ducts and migrate deeper into the kidney parenchyma. When irrigation is performed with a pressure pump set to 80 cmH2O or a gravity-driven irrigation bag, the pressure in the system is constantly increased to 60 cmH2O [25]. Each additional manual maneuver can cause a short-term, but strong pressure rise that boosts the intrarenal reflux. Because pelvic pressure is difficult to measure directly, multivariate analyses typically include factors that influence the pressure, like the type and rate of irrigation (inflow) or the UAS caliber (outflow). However, the latter has not been sufficiently tested in multivariate analyses for its effect on RIRS. Additionally, preparing the ureter with presteneting or dilatation with a srURS (outflow) might prove to be beneficial. All 17 included studies used the same type of irrigation between study groups; therefore, we could not assess the effects of different types. Only two studies assessed the effect of the irrigation rate on infectious complications, and both confirmed its independent predictive value [7, 11]. It is well known that irrigation is an important parameter; the trade-off between visibility and low irrigation pressure remains an unresolved dilemma for endourologists.

If we could have eliminated all contaminated cases, we might have found that comorbidities were important factors for predicting infectious complications. Indeed, comorbidities were previously associated with infectious complications related to percutaneous nephrolithotomies [26] and semi-rigid ureteroscopic lithotripsies [27].

Previous studies have shown that the ureteral stent dwell time prior to ureteroscopic surgery contributed to bacteriuria [28]. This association was not analyzed in the studies included in this review. However, we found that short-term presteneting was irrelevant, even in univariate analyses; thus, it was not investigated further.

We might expect the incidence of fever after RIRS to decrease with the surgeon’s experience. A previous propensity score analysis confirmed that surgeon experience was a significant independent factor for the risk of complications after a ureteroscopy [29]. However, none of the studies we included analyzed surgeon experience. Therefore, we could not address this factor. Consequently, the effect of surgeon experience on infectious complications after RIRS remains to be determined.

The distribution of parameters studied here clearly indicated a group of factors that were significantly associated with the occurrence of infectious complications after RIRS, although not all were well studied (Table 4). The remaining parameters listed in Table 3 were mostly considered insignificant. We could not investigate why they were considered significant in individual studies, because we lacked access to source data.
CONCLUSIONS

This systematic review confirmed that the operative time and a history of bacteriuria/infection were best studied independent risk factors in the incidence of infectious complications after RIRS. The most recent studies suggest that preoperative urinalysis may have higher predictive power than urine culture. Future multivariate analyses should focus on irrigation parameters, surgeon experience, comorbidities, long-term ureter stenting, and the interdependence of these variables.
