(Dated: November 8, 2018)

Recent work in two brane Randall-Sundrum models has shown that the radion can drive parametric amplification of particles on the TeV brane leading to a stage of cosmology similar to preheating. We consider radion induced preheating as a mechanism for electroweak scale baryogenesis and estimate the baryon to entropy ratio for some regions of parameter space. We also predict an upper bound for the radion mass, which makes this baryogenesis mechanism testable. Finally, we verify some assumptions with numerical calculations of the 1+1 dimensional Abelian Higgs model.

I. INTRODUCTION

The high degree of symmetry between matter and antimatter in our theories has long seemed in contradistinction with the overwhelming presence of matter (baryons) around us. Electroweak baryogenesis [1] provides a testable explanation of the baryon asymmetry within the context of the standard models of particle physics and cosmology but suffers from the two difficulties of providing enough CP violation and providing enough departure from equilibrium. In the usual picture transitions between vacua of the electroweak theory correspond, via an anomaly, to changes in baryon plus lepton number. If the electroweak phase transition in the early universe is strongly first order then the presence of CP violation will cause sphaleron transitions near bubble walls to favor formation of matter over anti-matter. While the minimal supersymmetric standard model may provide the first order phase transition and CP violation needed for this picture of baryogenesis, a radically different picture is possible within the context of the Randall-Sundrum model.

As with supersymmetry, the two-brane Randall-Sundrum model [2] (RS) provides a framework for addressing the hierarchy problem. The model consists of a slice of five dimensional anti-de Sitter space (AdS) truncated by two 3-branes with the standard model particles trapped on one of the branes. The gravitational warping between the branes generates hierarchies of mass scales. With the stabilization of the brane separation provided by Goldberger and Wise [3], mass scales are naturally stabilized providing a solution to the hierarchy problem along with an acceptable low-energy phenomenology. The separation between the branes corresponds to a particle called the radion which is expected to be the lightest new degree of freedom.

Initially, it might seem difficult to explain the baryon asymmetry within the context of RS since RS physics becomes important just above the electroweak scale. For example, it is not possible to use existing extensions of standard model physics to explain baryogenesis within an effective theory that integrates out RS physics. They are at the same scale. We must, therefore, re-examine the baryogenesis question within the context of the RS model. Fortunately, the radion provides a new route for departure from equilibrium; previous work has shown that homogeneous oscillations of the radion lead to exponential growth of scalar particles on the standard model brane [4]. The produced particles do not have a thermal distribution, but lie in a small region of momentum space. These are features common to parametric amplification, or preheating [5], as it occurs in the inflationary context.

We use parametric amplification of the standard model Higgs field to drive the field over the potential barrier, allowing for the creation of winding modes and, consequently vacuum transitions. This parametric amplification, rather than bubbles from a first order phase transition, generates the departure from equilibrium. With an additional source of CP violation, the decay of the Higgs windings will favor the production of baryons over antibaryons. However, there are constraints on the mass of the radion coming from the size of windings which give rise to baryon number violating transitions. Generically, if the radion is too massive, then the parametric amplification gives windings which are too small for baryogenesis. The radion should not be much more massive than three times the mass of the Higgs boson. Furthermore, because the radion is a gravitational mode in the full theory, the form of the radion-Higgs coupling is determined with only one free parameter (we consider only minimal coupling of the Higgs).

The next sections review relevant aspects of the standard model baryon violation and the RS model. We then discuss radion induced preheating and consequences for baryogenesis. We explain some constraints on the model and estimate the baryon asymmetry for a simple case. The final section shows numerical results which verify some assumptions and help develop our intuition.

II. BARYOGENESIS IN THE STANDARD MODEL

As alluded to above, non-perturbative effects in the electroweak sector of the standard model violate baryon number. An anomaly links the change in baryon and
lepton number to the change in Chern-Simons number:

$$\Delta B = \Delta L = n_f \Delta N_{CS}, \quad (1)$$

where $n_f$ is the number of families of matter fermions.

In the absence of fermions the vacua of this theory are degenerate and they are labeled by the winding number of the Higgs field. In any vacuum state the Chern-Simons number is equal to the Higgs winding number. The transition from one vacuum state to another must therefore involve a change in both the Higgs and gauge fields so that both the Higgs winding and the Chern-Simons number remain equal. See the reviews in [1] for more details. This baryon violating transition between vacua passes through a field configuration known as the sphaleron, which is a saddle point of the effective potential. Henceforth, we refer to the sphaleron mediated transitions between vacua as the sphaleron transition.

We can now understand that an initial configuration with the Higgs winding differing from the Chern-Simons number by one unit must relax to a vacuum in one of two ways: either the Higgs winding will change, which does not violate baryon number; or the gauge field evolution will change the Chern-Simons number, which does violate baryon number. The method by which the relaxation occurs is dependent upon the length scale of the winding. In general a Higgs winding will collapse and the time scale for the collapse is simply the length scale $R$. However, the gauge fields will evolve to cancel gradient energy in a Higgs winding with time scale loosely set by the gauge boson mass. So a sufficiently small winding will collapse and the Higgs winding number will change, while a sufficiently large winding will be canceled by the gauge field thus changing baryon number.

Some critical length scale separates these two regimes. If there is initially an equal density of windings and anti-windings on large scales and no CP violation, then there will be equal production of baryons and anti-baryons. According to the picture of Turok and Zadrozny [3], CP violation will affect the critical length differently for windings and anti-windings. An anti-winding near the critical scale will preferentially unwind through Higgs field evolution, while a winding at the same scale will unwind by gauge field evolution, thus favoring production of baryons. The critical length is about $3 m_W^{-1} \sim (30 \text{GeV})^{-1}$ if the gauge boson mass is given by the zero temperature vacuum. The realistic picture is more complicated with the length scale being a function of other parameters which characterize a winding, but there should still be a range of critical length scales separating Higgs field unwinding from baryon number changing.

In the high temperature, symmetry restored vacuum, simple dimensional analysis gives the sphaleron length scale as being the magnetic screening length, $(\alpha_W T)^{-1}$, which could be as large as about $(3 \text{GeV})^{-1}$. For the remainder of the paper we work with the length scale $l_{sph} = (20 \text{GeV})^{-1}$. We use this length scale to constrain the radion mass since a massive radion will give higher frequency excitations to the Higgs field leading to windings which are too small for baryogenesis.

At temperatures much below the electroweak scale, sphaleron transitions are exponentially suppressed by the energy scale of the potential barrier between electroweak vacua, $E_{sph} \sim 10 \text{TeV}$:

$$\Gamma_{sph} \sim e^{(-E_{sph}/T)}. \quad (2)$$

For temperatures near the electroweak scale and as low as $150 \text{GeV}$ [14], the electroweak symmetry is restored and the sphaleron transitions are unsuppressed.\(^1\) Thermal fluctuations easily form windings of the Higgs or gauge fields and on dimensional grounds

$$\Gamma_{sph} \sim (\alpha_W T)^4. \quad (3)$$

It might seem then that a temperature above $150 \text{GeV}$, along with CP violation, is sufficient for the production of baryons. However, the thermal average of baryon number is zero [1], meaning that baryogenesis must happen during a departure from thermal equilibrium. Furthermore, if equilibrium is restored while sphaleron transitions are unsuppressed, then any existing baryon asymmetry will be destroyed. This process is called thermal washout, and it will constrain the total energy in our model as explained in section [14].

**III. THE RANDALL-SUNDRUM SCENARIO**

The background geometry for the two brane Randall-Sundrum model (RS) is given by the metric

$$ds^2 = e^{-2kz} \eta_{\mu\nu} dx^\mu dx^\nu + dz^2, \quad (4)$$

with branes truncating the space at $z = z_0$ and $z = z_1$. This geometry is a solution to Einstein’s equations for negative bulk cosmological constant and nonzero brane tensions which scale with $k$. For naturalness $k$ is taken to be near the fundamental Planck scale, $M_5$, but somewhat smaller to ensure gravitational perturbativity. The warping of the space red shifts mass scales on the brane at $z_1$ relative to the scale at $z_0$, allowing for the electroweak theory trapped on the brane at $z_1$ to have an energy scale much less than scales on the brane at $z_0$. The brane at $z_1$ is therefore often called the $TeV$ brane. The separation between the branes corresponds to a modulus known as the radion. By fixing the radion in a natural way, the electroweak hierarchy problem is solved.

The form for the radion which does not mix with the four dimensional graviton $S$ is

$$ds^2 = e^{-2k(z+f(x))} g_{\mu\nu}(x) dx^\mu dx^\nu$$

\(^1\) Some authors [1] cite $100 \text{GeV}$ as the temperature above which sphaleron transitions are unsuppressed. We choose to follow reference [14] since a larger temperature is more conservative with respect to placing bounds on the radion mass.
and the value for the radion mass, $m$, canonical normalization, the action takes the form:

$$L_F = -\frac{1}{2} \partial_\mu F(x) \partial^\mu F(x) - \frac{1}{2} m_F^2 F(x)^2 + \mathcal{O}(F^3).$$  

We have rescaled $f(x)$ to have the properly normalized kinetic term,

$$F(x) = \sqrt{12kM_5^2 e^{k(z_1 - z_0)}} f(x)$$

and the value for the radion mass, $m_F$, depends on the details of the bulk scalar. The scale of physics on the $TeV$ brane is set by the parameter $\Lambda = \sqrt{3M_5^2/k e^{-k(z_1 - z_0)}}$. We will only consider small oscillations of the radion, $F(x) \ll \Lambda$, to avoid sensitivity to the higher order terms in the radion effective action.

Now consider a scalar field on the $TeV$ brane. We will see how the warping red shifts mass scales and derive the coupling of the radion to the scalar needed for the next section. We set $z_0 = 0$ for simplicity. The action on the brane is

$$S = -\frac{1}{2} \int d^4x \sqrt{-g} \left[ g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi + m^2 \phi^2 \right],$$  

with the induced metric on the brane given by

$$ds^2 = \tilde{g}_{\mu\nu}(x) dx^\mu dx^\nu = e^{-2k(z_1 + f(x) e^{2k z_1})} \eta_{\mu\nu} dx^\mu dx^\nu.$$  

By rescaling $\phi(x) \to e^{kz_1} \phi(x)$ to give the kinetic term canonical normalization, the action takes the form:

$$S = -\frac{1}{2} \int d^4x \left[ e^{-2kf(x)} e^{2k z_1} g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi + e^{-4kf(x)} e^{2k z_1} m^2 \phi^2 \right].$$  

Notice that the scalar field mass is suppressed by a “warp factor”, $e^{-kz_1}$. We define the effective scalar mass $m_\phi = e^{-kz_1} m$. In terms of the correctly normalized radion, the action is:

$$S = -\frac{1}{2} \int d^4x \left[ e^{-F(x)/\Lambda} \eta^{\mu\nu} \partial_\mu \phi \partial_\nu \phi + e^{-2F(x)/\Lambda} m_\phi^2 \phi^2 \right].$$  

IV. PREHEATING AND BARYOGENESIS

As we discussed in previous work [4], there may have been a time in the early universe when most of the energy density was tied up in coherent homogeneous oscillations of the radion. These oscillations might be expected for several reasons. First, an inflation-like mechanism is needed to solve the horizon problem within the RS context, and this mechanism almost certainly will involve physics of the extra dimension. In a minimal model the only way to reheat the $TeV$ brane is through the stabilization mechanism, which would involve oscillations of the stabilizing field and of the radion. We take the potential of the stabilizing field to be stiff and study oscillations of the radion.

Alternatively, at high enough temperatures the spacetime is unstable to formation of a bulk horizon, which cuts off the space and removes the $TeV$ brane. As the universe cools, a phase transition occurs [2], generating the $TeV$ brane generically shifted from its equilibrium position. The radion will oscillate coherently as the brane settles in to the equilibrium position. In this scenario we would not expect a cold $TeV$ brane, although more details of this phase transition still need to be understood.

In a third picture, the stabilization mechanism may provide a false vacuum for the radion with the $TeV$ brane at infinity [10]. Early universe dynamics could set the brane in this false vacuum with a first order phase transition bringing the brane to the global minimum. Bubbles of the brane in the true vacuum would not be expected to lie exactly at the bottom of the potential, but oscillate around the minimum. In any of these three scenarios, higher energy physics leads to radion oscillations.

We take the radion to be a background of the form

$$F(t) = F_0 \cos(m_F t),$$  

and decompose the scalar field in Fourier modes:

$$\phi(t, \vec{x}) = \int \frac{d^3k}{(2\pi)^{3/2}} \left[ a_k \phi_k(t) e^{-i\vec{k} \cdot \vec{x}} + a_k^* \phi_k^*(t) e^{i\vec{k} \cdot \vec{x}} \right].$$  

We then calculate the equation of motion for the scalar modes from the action [11]:

$$\frac{d^2 \phi_k}{dt^2} + F_0 m_F \sin(m_F t) \frac{d\phi_k}{dt} + \omega_k^2(t) \phi_k = 0,$$

where $\omega_k^2(t) \equiv |\vec{k}|^2 + m_\phi^2 e^{-F_0 \cos(m_F t)}$. We start with a vacuum state for all modes,

$$\frac{d\phi_k}{dt}(0) = -i \omega_k(0) \phi_k(0), \quad \phi_k(0) = \frac{e^{F_0/2}}{\sqrt{2\omega_k(0)}},$$

and find exponential growth of some modes. For the specific case $F_0 = 0.5$, the modes unstable to growth are shown in the dark region of figure [11]. This is parametric resonance, or preheating.
It should be emphasized that the spectrum of particles produced through parametric amplification is non-thermal and the time scale for growth of particles is given by the radion mass. To show this we calculate the expectation value of the number density operator, \( \langle N_k(t) \rangle \) (see the appendix for details). In figure 2 we plot \( \ln \langle N_k(t) \rangle \).

The modes in momentum space which grow are those expected by comparing with figure 1. We expect that when backreaction of the scalar on the radion is taken into account, the scalar will drain energy off the radion and damp the amplitude of radion oscillations.

We now want to think about placing the Standard Model on the TeV brane. Again assuming homogeneity and an initial state near the zero temperature vacuum, we would expect Higgs particle production as explained above, where \( m_\phi \) is now the Higgs mass. Of course, the action for the Higgs field should involve the self-coupling and the coupling to gauge fields. However, leaving these terms out should be a good approximation at the beginning when only the minimum of the potential is being sampled by the Higgs vacuum expectation value. The choice of initial conditions is generalized in the numerical work. We discuss production of fermions and gauge fields below.

The essence of the idea is that the preheating of the Higgs field will produce configurations with winding, in a manner analogous to the production of topological defects following inflationary preheating. These windings will then decay. Some decays will violate baryon number, some will not, and the CP violation will favor production of a small number of net baryons. A similar idea of inflationary preheating leading to baryogenesis has been proposed by others [10, 11]. However, radion preheating occurs naturally at the proper energy scale, the electroweak scale, and has little freedom in parameter space due to the universality of radion couplings. These concepts are significant: there is no fine tuning needed, as in the inflationary case, to make radion preheating happen at the correct energy scale; and our model will be tested and may be excluded at the next generation of colliders.

### A. Constraints

Before estimating the amount of baryogenesis, we would like to discuss some constraints on the radion. First, the final reheat temperature should be sufficiently below the electroweak phase transition to avoid thermal washout of the baryon asymmetry. If, once thermal equilibrium is reached, we require

\[
T_{\text{reheat}} \lesssim 150 \text{ GeV},
\]

then we must constrain the total energy density:

\[
\rho = \frac{\pi^2 g_* T^4}{30} \lesssim (350 \text{ GeV})^4.
\]

Because the expansion rate of the universe, \( H \sim \sqrt{T/\rho_{\text{pl}}} \sim 10^{-15} \text{ GeV} \), is much less than other relevant scales in the problem, we may ignore the expansion. Then energy conservation restricts the initial radion configuration:

\[
\rho_F = \frac{1}{2} F_0^2 A^2 m_F^2 \lesssim (350 \text{ GeV})^4.
\]
for sphaleron configurations, \( l_{\text{sph}} \), is about \((20 \text{ GeV})^{-1}\). The instability band therefore needs to encompass this value of momentum in order to produce sphaleron configurations. For the case considered in figure 3, this criteria is only satisfied for a radion mass of \( 1.5 \lesssim m_F / m_\phi \lesssim 3 \). More generally, we can understand this constraint by plotting the instability band as a function of \( F_0 \) and \( m_F \) for fixed \( k = l_{\text{sph}}^{-1} \) as in figure 2.

The region above the line is excluded by the energy density constraint. This assumes a Higgs mass of 125 GeV, to set a scale, and a fairly low value for the cutoff, \( \Lambda = 750 \text{ GeV} \). These values are used in the remainder of the paper. Equation (18) shows that this line moves down (excluding more of the preheating band) as the lower limit of the cutoff increases or if the Higgs mass becomes heavier. Already we can see that if the radion mass is much above three times the Higgs mass, then there can be no preheating without thermal washout of baryons. For a light radion we need large values of \( F_0 \) for preheating. To trust a calculation in this regime requires knowledge of the complete radion potential. This involves details of the stabilizing mechanism.

While \( O(F^3) \) and higher terms in the radion action will alter the form of radion oscillations and make a precise large \( F_0 \) calculation of the baryon to entropy ratio difficult, in practice, these terms do not prohibit parametric amplification of the Higgs field. A simple numerical calculation similar to that shown in figure 2 demonstrates that arbitrary \( O(\Lambda) \) and \( O(1) \) coefficients for \( F^3 \) and \( F^4 \) terms respectively preserve exponential growth of the Higgs fluctuations. The significant concern for the purposes of this paper is that higher terms would modify the location of the instability band without a comparable modification of the energy density constraint, thus altering the upper limit on the radion mass. While we can’t rule out this possibility, it does not seem to be a generic feature of these operators.

**B. Evolution**

We may estimate when sufficient preheating has occurred to form Higgs windings by calculating the two point correlation function of the Higgs fluctuations. We work in a toy model with no gauge fields. Shifting the Higgs field,

\[
\phi = \varphi + \chi, \quad \varphi \equiv \langle \phi \rangle,
\]

the equation of motion for the vacuum expectation value (VEV) of the Higgs in the Hartree approximation becomes:

\[
\Box \varphi + \lambda (\varphi^2 - v^2 + 3\langle \chi^2 \rangle) \varphi = 0.
\]

In the electroweak theory windings will be able to form when the Higgs VEV crosses the potential barrier. In this toy theory, \( \varphi \) crosses the barrier when this two point function is of the order of the zero temperature vacuum expectation value:

\[
\langle \chi^2 \rangle \sim v^2 / 3.
\]

It is not clear that the system will necessarily behave as if the symmetry of the vacuum for \( \varphi \) has been restored, but we do not need to concern ourselves with this issue. We only need the fluctuations, \( \langle \chi^2 \rangle \), to kick the field across the potential barrier for winding formation.

In figure 4, we plot \( \langle \chi^2 \rangle(t) - \langle \chi^2 \rangle(0) \) where

\[
\langle \chi^2 \rangle(t) = \int_0^\Lambda \frac{d^3k}{(2\pi)^3} |\chi_k(t)|^2.
\]

The equation of motion for the Fourier modes, \( \chi_k \), is given by equation (14) where \( \phi_k \) is replaced by \( \chi_k \) and \( m_\phi \) is now the Higgs mass. We start again with vacuum initial conditions as in equation (15). From the plot it is clear that the winding formation condition, equation (21), is satisfied after a few radion oscillations. Of course, at this point the approximation of linearizing the equations has broken down. We are simply making the point here that windings should form on a time scale set by the radion mass. Because \( \langle \chi^2 \rangle \) is cutoff dependent even in the initial vacuum state, we plot the change in this quantity.

There are several possible times scales relevant to this problem. First, the Hubble scale, is often important in electroweak baryogenesis since the Hubble expansion
cools the universe and causes the sphaleron transitions to freeze out. Here that role is played by the thermalization time scale and the Hubble parameter is irrelevant. The sphaleron transitions freeze out as the energy in the Higgs field is redistributed to all the other degrees of freedom in the standard model. The total decay rate of the Higgs boson is near $10^{-2}\text{GeV}$ so we assume this determines the thermalization time scale. We take the sphaleron time scale to be the length scale, $l_{\text{sph}}$, which is much shorter than the thermalization scale. Finally, the fourth time scale is that of preheating. As we have seen above, the preheating scale is given by the radion mass.

This picture is not significantly altered by the presence of matter fermions or gauge fields. Pauli blocking prevents the exponential growth of fermions, and the decay time scale of the Higgs boson is much longer than the preheating scale. Fermions can safely be ignored. The radion also couples to the gauge fields, but not to the kinetic term. Without the derivative coupling that was present between the radion and the Higgs in equation (14), there is much less parametric amplification. The full sphaleron transition naturally involves gauge fields, but here we focus on generation of the Higgs windings only and leave more detailed study for future work.

C. An Estimate

For generic parameters inside the preheating band of figure 3 the radion will continue to produce windings of the appropriate length scale for much longer than the sphaleron time scale. This winding production time will depend on the total radion energy and on the thermalization time scale for the system. For example, in figure 11 only about $1/10$ of the energy of the radion has gone into the Higgs field by the time windings form. We expect baryon production to be quite efficient here, since sphaleron transitions may take place throughout the entire brane during preheating. To calculate the baryon asymmetry, though, will require a deeper understanding of the sphaleron transition rate in this far from equilibrium state. It will also require the full $SU(2)$ Higgs and gauge fields, a better understanding of the thermalization time scale, and, of course, a source of CP violation. There has been work on this calculation within the context of baryogenesis following inflation. Some efforts have applied ideas from thermal sphaleron transitions [11], while others have applied lattice calculations [12, 13]. These steps are important, but difficulties may remain [10].

Nevertheless, for some specific choices of $F_0$ and $m_F$, it may be possible to estimate the winding density of the Higgs field and acquire insight on the baryon asymmetry in a manner which is independent of a new CP violating mechanism. If the radion preheating generates windings and shuts off on a time scale shorter than the sphaleron time, then the Higgs winding density can be estimated via the Kibble mechanism. To see how this might happen, we plot the instability band as a function of $F_0$ and momentum in figure 5 for radion mass $m_F = 2.5m_\phi$. Considering the backreaction of the Higgs field on the radion, we expect a smaller $F_0$ to be relevant later as the radion loses energy to the Higgs field.

So, if the system starts near $F_0 = 0.3$, then sphaleron sized windings may occur for a time $\sim l_{\text{sph}}$. As $F_0$ decreases, much of the remaining energy of the radion will be dumped to higher momentum modes centered around $k = 0.75m_\phi$. Then, much as happens in defect formation through inflationary preheating, we expect that there will be one winding per $l_{\text{sph}}^3$ region of space. In this process the quantum fluctuations are being amplified, and unless there is reason to expect long range correlations, then causally disconnected regions should wind in different directions.
We may now make our estimate. We calculate the entropy present:

\[ s = \frac{2\pi^2}{45}g_s T^3, \]

where the temperature after thermalization is given by the energy density for \( T_0 = 0.3 \), and \( m_T = 2.5m_\phi \), along with equation (17): \( T \approx 0.75 m_\phi \). We parameterize the CP violation such that the baryon density is the product of the winding density and \( \epsilon_{cp} \):

\[ B = n_w \epsilon_{cp}. \]

Then the baryon to entropy ratio becomes

\[ \eta = \frac{B}{s} \approx \frac{l_{ph}^{-3} \epsilon_{cp}}{s} \approx 10^{-4} \epsilon_{cp} \]

The measured value is \( \eta \approx 10^{-10} \). Note that the strong dependence of the winding density to the sphaleron time scale makes this estimate imprecise.

It is common in four dimensional scenarios to postulate that a nonrenormalizable CP violating term arises from a higher energy theory. The same may be possible here, but any higher energy theories need to live in the bulk. It would be interesting to investigate the details of bulk CP violation and the consequences for baryogenesis on the brane. It may also be possible to add the CP violation on the brane at electroweak energies, as in a two Higgs doublet model.

V. A NUMERICAL MODEL

To see some details of this process borne out more explicitly, we now turn to a numerical implementation of the 1+1 dimensional Abelian Higgs model. This model has features in common with the baryon violation in the standard model, as we will see below, and has therefore often been used in the past to study baryogenesis [1]. The Abelian Higgs model allows us to go beyond the linearized equations and to include backreaction on the radion without the technical difficulties of solving a non-Abelian model numerically. We can study the formation of winding modes and confirm our intuition that the length scale of the windings is given by the location of the instability band.

The action for our toy theory is

\[ S = \int d^2x \left( -\left( D_\mu \phi \right)^\dagger D^\mu \phi - \frac{1}{4} F_{\mu \nu} F^{\mu \nu} - \frac{\lambda}{4} \left( \phi^\dagger \phi - \nu^2 \right)^2 \right). \]

In the vacuum the scalar sits at the bottom of the potential well

\[ \phi = v e^{i \theta(t,x)} \]

and \( A^\mu \) is pure gauge

\[ A_\mu = \frac{1}{e} \partial_\mu \theta(t,x). \]

This theory has a winding number which labels the vacua

\[ N_H(t) = \frac{1}{2 \pi} \int dx \partial_\theta, \]

and transitions between vacua require \( \phi \) to pass through zero. In addition, the Chern-Simons number is proportional to the Higgs winding number in the vacuum state:

\[ N_{CS} = \int dx A_x = \frac{2\pi}{\Lambda} N_H. \]

Thus the vacuum structure of this theory resembles that of the electroweak sector of the standard model. With the addition of fermions there is a conserved chiral current, which is anomalously broken in a way that is related to the change in Chern-Simons number [17], \( \Delta(N_R - N_L) = \Delta N_{CS} \).

Because the radion, which stabilizes a slice of \( AdS_5 \), does not couple as the 5 dimensional radion, we introduce a "radion" designed to mimic the 3+1 dimensional preheating. As mentioned above, we are primarily interested in the early time behavior and specifically the formation of the Higgs windings modes. Therefore, we restrict our attention to the radion-Higgs sector:

\[ S = \int d^2x \left( -\frac{1}{2} e^{-F/\Lambda} \eta^{\mu \nu} \partial_\mu \phi^\dagger \partial_\nu \phi 
- \frac{1}{4} e^{-2F/\Lambda} \left( \phi^\dagger \phi - \nu^2 \right)^2 \right). \]

We start the Higgs field in a vacuum state as before. We then briefly evolve the linearized quantum equations [14]. After particle production has begun, but before equation (21) is satisfied, we Fourier transform to configuration space and evolve the full non-linear classical equations of motion. In other words, the quantum field with a few particles is serving as the initial configuration of the classical field for our classical evolution. We checked that results are not sensitive to the time when the transition from quantum to classical evolution occurs. Because of the exponential growth in the preheating band, results are also relatively insensitive to random changes in the initial conditions, equation [18], by factors of 4 or more. With such large initial fluctuations, there are more windings at early times, but after several oscillations of the radion there is not a significant difference. However, an initially hot brane, or a brane with any non-trivial initial energy density, does make a change to the reheat constraint, equation [18] since it is the total energy density which is constrained by equation [17]. So initial energy density on the brane will move the line

\[ \Delta N_{CS} = \int dx A_x = \frac{2\pi}{\Lambda} N_H. \]

\[ \Delta N_{CS} = \int dx A_x = \frac{2\pi}{\Lambda} N_H. \]

2 After our work was completed, reference [18] appeared using the same method of setting initial conditions for the classical field.
in figure down, thus excluding more of the preheating band.

In figure we show the phase of the Higgs field after windings have begun to form. We want to know the length scales of the windings. At early times, as in figure windings are easy to identify since the fluctuations in phase have not grown too large. We define the length of winding as being the minimum distance between two points separated in phase by 2π. In figure we show the number of windings as a function of length scale for two cases with \( \mathcal{F}_0 = 0.5 \), as in figure. The curve peaked at smaller scales corresponds to the more massive radion, which has a preheating band at larger values of momentum. This is what we expect. For the case with longer length windings, \( m_F = 2.0 m_\phi \), there are about 1200 windings. This corresponds to about one winding in every 10 causal volumes. The other scenario, \( m_F = 4.0 m_\phi \), preheats more efficiently, in part because the radion oscillates more quickly leading to about one winding in every 2 causal volumes. In both cases the winding density is increasing quickly with time.

It would be interesting to use numerical methods on the classical 3+1 dimensional \( SU(2) \) theory to track the Chern-Simons and Higgs winding numbers. The dependence of these quantities on the radion mass should unambiguously confirm or refute the model. In addition, this calculation would provide a more concrete estimate of the range of baryon to entropy ratios possible.

VI. CONCLUSION

We have shown that baryogenesis can occur in the two-brane Randall-Sundrum model with radion preheating providing the departure from equilibrium. Another source of CP violation is needed, and as mentioned, investigations of bulk CP violation may prove interesting. One of the successes of this model is that preheating occurs naturally at the energy scale for sphaleron transitions to generate the asymmetry, but not wash it out.

Furthermore, the existence of a baryon asymmetry in our universe implies an upper bound on the radion mass. For a sufficiently large radion mass, the preheating band does not extend down to sphaleron length scales, unless the radion energy exceeds the thermal washout limit. We conclude that the radion mass should not be much larger than three times the Higgs mass, if the baryon asymmetry is to arise from this model.

APPENDIX: NUMBER DENSITY OPERATOR

We calculate here the expectation value of the number density operator, \( \langle 0 | \hat{a}_k^\dagger(t) \hat{a}_k(t) | 0 \rangle \), for a massive scalar field coupled to the radion, i.e. for action \( \mathcal{L} \). First, let us change the notation slightly to ease this calculation. We decompose the scalar:

\[
\phi(t, \vec{x}) = \int \frac{d^3k}{(2\pi)^{3/2}} \hat{\phi}_k(t) e^{-i\vec{k} \cdot \vec{x}}, \tag{A.1}
\]

where

\[
\hat{\phi}_k(t) = U_k(t) \hat{a}_k + U^*_k(t) \hat{a}^\dagger_{-k}.
\tag{A.2}
\]

We decompose the conjugate momentum, \( \pi(t, \vec{x}) \), in the analogous manner and find

\[
\hat{\pi}_k(t) = e^{-F(t)/\Lambda} \left( \hat{U}_k(t) \hat{a}_k + \hat{U}^*_k(t) \hat{a}^\dagger_{-k} \right).
\tag{A.3}
\]

We have assumed that the radion is independent of the spatial coordinate in anticipation of homogeneous oscillations.

This decomposition is in terms of operators which annihilate the initial vacuum, \( \hat{a}_k | 0 \rangle = 0 \). We seek an expression for time dependent operators, \( \hat{a}_k(t) \), in terms of the initial time operators so that we may calculate the number of particles relative to the initial vacuum. The
time dependent (Heisenberg picture) operators must satisfy the equation of motion

\[
d\frac{d}{dt} \hat{a}_k(t) = [\hat{a}_k(t), H(t)], \tag{A.4}
\]

where \(H(t)\) is the Hamiltonian. The Hamiltonian can be written in terms of \(\hat{\phi}_b(t)\) and \(\hat{\pi}_b(t)\):

\[
H(t) = \frac{1}{2} \int \frac{d^3k}{(2\pi)^3/2} \left[ e^{F(t)/\Lambda} \hat{\pi}_k(t) \hat{\pi}_k(t) - e^{-F(t)/\Lambda} \hat{\phi}_k(t) \hat{\phi}_k(t) \right]. \tag{A.5}
\]

As in the main text, \(\omega_k^2 = k^2 + m^2 e^{-F(t)/\Lambda}\). We may look for a solution by making the ansatz:

\[
\hat{\alpha}_k(t) = g(t) \hat{\pi}_k(t) + h(t) \hat{\phi}_k(t). \tag{A.6}
\]

This guess is motivated by a form of Bogoliubov transformation and the knowledge that \(\hat{\pi}_k(t)\) and \(\hat{\phi}_k(t)\) contain all of the degrees of freedom of the system. From the initial conditions, \(\hat{\alpha}_k(t=0) = \hat{a}_k\), and

\[
dU_k(0) = -i\omega_k(0)U_k(0), \quad U_k(0) = e^{F(0)/2/\Lambda}/\sqrt{2\omega_k(0)}, \tag{A.7}
\]

as in equation (11b), we find the initial values:

\[
g(0) = iU_k(0) \quad h(0) = -ie^{-F(0)/\Lambda}U_k^*(0). \tag{A.8}
\]

Finally, using the standard equal time commutation relations for the field, \([\hat{\phi}_k(t), \hat{\pi}_b(t)] = i(2\pi)^3 \delta^3(\vec{k} + \vec{p})\) we may evaluate the equation of motion for \(\hat{\alpha}_k(t)\). The result is simple:

\[
d\frac{d}{dt} g(t) = 0 = d\frac{d}{dt} h(t). \tag{A.9}
\]

We now use the form for the oscillating radion given in the text in equation (12) and evaluate the number operator from the ansatz (A.6):

\[
\langle N_k(t) \rangle = \langle 0 | \langle \hat{a}_k(t) \hat{a}_k(t) | 0 \rangle = \frac{e^{-F_0} \left[ e^{2F_0} [1 - \cos(m_F t)] | \hat{U}_k(t) |^2 + \omega_k^2(0) | \hat{U}_k(t) |^2 \right]}{2} - \frac{i e^{-F_0} \cos(m_F t)}{2} \left[ \hat{U}_k(t)^* \hat{U}_k(t) - \hat{U}_k(t) \hat{U}_k(t)^* \right]. \tag{A.10}
\]

ACKNOWLEDGMENTS

I would like to thank Rich Holman for valuable discussion and Mark Trodden for useful comments on the manuscript. This work was supported by DOE grant DE-FG03-91-ER40682.
