Abstract

Background: Hydranencephaly is a congenital abnormality of the central nervous system characterized by massive hemispheric necrosis and ventricular dilatation with most of the cerebral hemispheres being replaced by membranous sacs filled with cerebrospinal fluid (CSF). Cytomegalovirus (CMV) infection can be one of the causes of hydranencephaly. The choice of therapy for hydranencephaly is a challenge because of poor prognosis, but now neural stem cell (NSC) transplantation may give new hope.

Case report: We report a case of a female newborn born at term by cesarean section from a gravida 5, para 3, abortus 1 (G5P3A1) mother with suspected hydrocephalus. Head circumference was 35 cm at birth. The baby was born crying immediately, looked active, and did not appear cyanotic, but on the second day, the baby looked less active, moaned, showed acral cyanosis, and had a large fontanelle that was dilated and soft. Signs of hydrocephalus such as Macwen's sign, setting sun phenomenon, and transillumination were found to be positive. Echocardiographic examination showed floppy interatrial septum and mild mitral regurgitation. Non-contrast computerized tomography (CT) scan of the head showed hydranencephaly. The toxoplasmosis, rubella, CMV, and herpes simplex virus (TORCH) screening showed positive anti-CMV immunoglobulin G (IgG). The baby underwent a ventriculoperitoneal (VP) shunt procedure with a head circumference of 36 cm before surgery. VP shunt was performed with an opening pressure of 15 cmH₂O.

Conclusions: After the VP shunt procedure, the baby's general condition improved with the head circumference within normal limits. The baby was discharged from the hospital after 16 days of treatment.

Introduction
Hydranencephaly is an uncommon congenital abnormality of the central nervous system. It is characterized by massive hemispheric necrosis and ventricular dilatation with most of the cerebral hemispheres being replaced by membranous sacs filled with cerebrospinal fluid (CSF). This abnormality is very rare and unique with an incidence rate of less than one per 10,000 births in the world. 

Although there are many studies on hydranencephaly, some aspects of hydranencephaly are still being debated in terms of pathogenesis, onset, clinical manifestations, and prognosis. Intrauterine lesions to the bilateral supra-clinoid internal carotid arteries are thought to be the underlying pathophysiology of hydranencephaly, which leads to resorption of brain tissue usually supplied by the anterior circulation. Intrauterine infections and toxin exposure have been suggested as possible causes of these vascular damages. Congenital cytomegalovirus (CMV) infection can be one of the causes of hydranencephaly, but it is very rare. In a retrospective cohort study, macrocephaly (92%) was the most common clinical manifestation of hydranencephaly, followed by seizures or myoclonic movements (41%), and signs of increased intracranial pressure (ICP) (25%).

The choice of therapy for hydranencephaly including CSF diversion surgery is a challenge in itself because the prognosis is quite poor. Neural stem cell (NSC) transplantation therapy may be a new hope as an option for hydranencephaly therapy. We report a case of a female newborn with hydranencephaly and congenital cytomegalovirus infection and underwent a ventriculoperitoneal (VP) shunt procedure.

Case report
A female Javanese newborn was born from a 35-year-old mother, gravida 5, para 3, abortus 1 (G5P3A1), at the gestational age of 38 weeks. The baby was born by cesarean section on indication of suspected hydrocephalus with a birth weight of 3000 grams, body length 49 cm, head circumference 35 cm and chest circumference 32 cm, and an Appearance, Pulse, Grimace response, Activity, Respiration (APGAR) score of 8-9-10 at 1.5 and 10 minutes. The baby was born crying immediately, looked active, and did not appear cyanotic. The infant's primitive reflexes were intact at birth. The baby care after birth was performed in the perinatology room.

The mother did not partake in any antenatal care during pregnancy. She admitted that she did not have any complaints or flu-like syndrome during pregnancy. A family history of congenital abnormalities was denied. From her previous obstetric history, the mother had experienced abortion once during her second pregnancy with unknown causes.
On the second day, the baby looked less active, moaned, showed acral cyanosis, and had a large fontanelle that was dilated and soft. Signs of hydrocephalus such as Macewen’s sign, setting sun phenomenon, and transillumination were found to be positive. From the babygram examination, neonatal pneumonia was suspected, while the echocardiographic examination indicated a floppy interatrial septum and mild mitral regurgitation (Figure 1). The non-contrast computerized tomography (CT) scan of the head showed a hypodense lesion according to the density of CSF filling the right and left hemicrania, while the hemi-cerebral cortex and lateral and third ventricles were not visible. Structures of the right thalamus, mesencephalon, pons and posterior fossa, and falx cerebri were still visible. The non-contrast CT scan of the head indicated hydranencephaly (Figure 2). From the toxoplasmosis, rubella, CMV, and herpes simplex virus (TORCH)
screening examination, the results of anti-CMV immunoglobulin G (IgG) were 22 aU/ml (positive if the value \( \geq 6 \)) and anti-CMV IgM were 0.156 COI (negative if the value \( \leq 0.7 \)).

On the 6th day, the baby had bradypnea and then apnea. The baby was then intubated with no. 3.5 endotracheal tube (ETT), 9 cm deep, and attached to mechanical ventilation with pressure control mode, inspiratory pressure (Pinsp) 13 cmH\(_2\)O, positive end-expiratory pressure (PEEP) 8 cmH\(_2\)O, respiratory rate (RR) 40, fraction of inspired oxygen (FiO\(_2\)) 80%, and inspiratory expiratory ratio (I/E) 1:2. The baby care was moved to the neonatal intensive care unit (NICU) room. The baby seemed to have jitteriness.

After discussions with the patient's family, we decided to perform a VP shunt procedure. Head circumference before surgery was 36 cm (large for gestational age based on the Lubchenco curve). The VP shunt was performed with an opening pressure of 15 cmH\(_2\)O. CSF was taken for macroscopic, chemical (protein, glucose, albumin), and microscopic (erythrocyte, leukocyte, foreign cell) analysis and the results were within normal limits.

After the VP shunt procedure was performed, the baby's general condition improved. The baby's head circumference was within normal limits according to the Lubchenco curve with an average of 33 cm. Oxygen weaning was done gradually until the baby could breathe in room air on the 15th day of treatment. On day 16, the baby fully recovered and later discharged from the hospital weighing 3000 grams and scheduled for follow-up examination and routine physical rehabilitation.

**Discussion**

Hydranencephaly is a condition in which there is no cerebral tissue because most of the brain's lining is damaged, fluid, and reabsorbed. The cerebral hemispheres are largely replaced by the thin-walled leptomeningeal sacs filled with CSF, preserving the structures of the midbrain and cerebellum. In hydranencephaly, there is a partial or complete falx cerebri structure with brainstem atrophy and the cerebellum is almost always normal, distinguishing it from holoprosencephaly.\(^8,9\) According to the patient in this case, brain structures other than the cerebral cortex were still visible.

In the absence of most of the cerebral cortex, the fetal head should be small. However, in some cases, the head is more often normal or enlarged because the choroid plexus in the lateral ventricles continues to produce CSF that cannot be adequately absorbed, causing an increase in pressure that can expand and impair the integrity of the ventricles and other intracranial structures.\(^10\)

Several studies have stated that the onset of hydranencephaly is still debated and has not been proven. Most refer to the second trimester of pregnancy at 13 to 26 weeks after the hemispheres, ventricles, and falx cerebri are formed, followed by ischemic damage occurring in the third trimester, which usually causes multicystic encephalomalacia.\(^2,8,11,12\) However, there are also some case reports of hydranencephaly diagnosed before the 12th week of gestation, so hydranencephaly may occur in the first trimester of pregnancy.\(^2,13–15\)

The cause of hydranencephaly remains unclear. Several hypotheses suggest vascular occlusion and infection be the causes of hydranencephaly.\(^5\) Occlusion of the supra-clinoid segment of the bilateral internal carotid artery is the most common cause, but this has not been confirmed because in some autopsies of hydranencephaly cases, the internal carotid arteries are not always occluded.\(^7,8\) Other causes include extensive tissue necrosis with cavitation, resorption of necrotizing tissue, and necrotic vasculitis caused by maternal exposure to carbon monoxide or butane gas. Intrauterine infections, such as congenital toxoplasmosis, CMV, and herpes simplex, can also cause local brain tissue damage.\(^16\) Hydranencephaly is not a malformation, but rather a secondary disorder of some pathological event, which causes ischemia in the uterus in the carotid artery area.\(^5\)

The screening result of the patient in our case found evidence of congenital CMV infection. CMV target cells are immature cells of the germinal matrix that result in extensive periventricular inflammation, tissue necrosis, and dystrophic calcifications. In early pregnancy, neuronal migration anomalies can occur and subsequent infection can cause encephalopathic disorders, such as subependymal paraventricular cysts, hydranencephaly, and microencephaly.\(^17\)

After CMV infects the fetus, several types of fetal cells allow CMV to replicate; including endothelial, epithelial, smooth muscle, and mesenchymal cells, as well as hepatocytes, monocytes or macrophages, and granulocytes. In further studies, CMV infection was also identified in several organs, such as the adrenal glands, bone marrow, diencephalon, small intestine, spleen, and heart.\(^17\) From the case presented in the current report, the patient also had cardiac abnormalities, which may have been caused by congenital CMV infection.
CMV-immunoglobulin M (IgM) antibodies are used as an indicator of acute infection, whereas IgG antibodies begin to appear after the onset of infection for several months. However, in cases of congenital infection, detection of CMV-IgG antibodies is complicated by the transplacental transfer of maternal antibodies. The results of the CMV antibody examination of the patient in this case report showed positive anti-CMV IgG with negative anti-CMV IgM, which supports the possibility that this infection was not an acute episode and was associated with the process of hydranencephaly. According to research from Chen et al., acquired anti-CMV IgG in infants disappears before the age of 8 months.

Antiviral treatment should be given to infants with virologically confirmed congenital CMV infection. Intravenous ganciclovir and its orally available prodrug, valganciclovir, is the antiviral agent recommended for the treatment of congenital CMV disease. The patient in this case was not given antiviral treatment for CMV because the infection was not an acute episode.

Most babies with hydranencephaly die before birth. Infants that survive usually do not show visible neurological or clinical signs at first; primitive reflexes such as the sucking and swallowing reflexes, movements of the legs and arms are frequently present at birth. More specific symptoms, such as moaning, difficulty eating, hypotonia, or a dilated fontanelle, may also be present. After a few days, symptoms such as severe hypotonia, irritability, and seizures become more noticeable. The patient's initial signs found in this case report were that the baby looked normal at birth, but on the second day the large fontanelle dilated, movement became less active and on the 6th day, the patient appeared to have jitteriness.

Hydranencephaly has a poor prognosis because of the loss of most brainstem functions. Patients generally die before birth or within the first year of life. Treatment of hydranencephaly is only supportive and symptomatic, and the choice of therapy should be discussed with the family in detail. The failure of surgery to improve cognitive function must be balanced with stabilization of increased ICP and head size. The VP shunt procedure is an option but may require some repairs because there may be leakage from the hole site and absorption problems in the peritoneum. In this patient a VP shunt procedure was performed with consideration for stabilization of increased ICP and head size.

The risk of complications of a VP shunt in infants with extreme macrocephaly is increased because of thinning and fragility of the scalp, malnutrition, and infected scalp ulcers. In infants with this condition, the choroid plexus coagulation procedure might be considered due to its higher success rate compared to ventriculoperitoneal shunt based on several studies.

NSC transplant therapy that has been successful in animal models is a new hope. Success is also seen in cerebral palsy patients with an effectiveness of about 50%. Hypothetically, cell junction pathology is the final common pathway of various genetic and environmental factors that cause disturbances in the ventricular zone (VZ). VZ disorders in the cerebral aqueduct cause hydrocephalus, while VZ disorders in the telencephalon cause abnormal neurogenesis. NSCs are known to have self-sustaining and pluripotent properties.

Proliferation and migration of neurons occur between the 12th and 30th weeks of gestation in humans, whereas in fetuses with hydrocephalus, VZ disturbances begin around the 16th week of gestation and continue throughout the second and third trimesters of gestation. NSC transplant surgery is generally performed ex-utero after the child is born, but ideally, NSC transplantation is performed at an early stage of fetal development during the process of forming neurons in the cortex during VZ disruption. In-utero fetal surgery is a recent advancement that allows the operation to be safer by considering the safety of the mother and fetus, as well as avoiding premature delivery. Unfortunately, there are no facilities available at this time to accommodate the implementation of NSC transplantation at our location. Hydranencephaly generally has poor prognosis, however there are several reports showing hydranencephaly patients able to survive for more than 5 years. The patient survival depends on the integrity of their brainstem function which controls cardiorespiratory function as well as temperature regulation. According to several studies comparing CPC and ventriculoperitoneal shunt, it is shown that CPC has higher success rate, however due to lack of neuroendoscopic facilities in developing countries such as Indonesia, especially in rural area, ventriculoperitoneal shunt was chosen in our study and showed improvement in patient's condition.

Conclusions
We report a case of hydranencephaly in a newborn with congenital CMV infection who underwent a VP shunt procedure. Hydranencephaly in our patient was a congenital central nervous system abnormality that may have been caused by intruterine CMV infection. Despite having a poor prognosis, the patient improved after undergoing a VP shunt procedure. The success of NSC transplantation therapy in animal models and cerebral palsy patients may be a new hope for the treatment of hydranencephaly. Unfortunately, there are no facilities available at this time to accommodate the implementation of NSC transplantation at our location.
Data availability
All data underlying the results are available as part of the article and no additional source data are required.

Consent
Written informed consent for publication of their clinical details and clinical images was obtained from the parent of the patient.

Hydranencephaly is an uncommon congenital abnormality of the central nervous system. This article reported a rare case of a female newborn with hydranencephaly and congenital cytomegalovirus infection, who underwent a ventriculoperitoneal (VP) shunt procedure successfully.

This article was very interesting, but I think it needs some modifications and answers to the questions:

1. Did the patient need medical care at the time of discharge?

2. It is true that the prognosis of hydranencephaly is poor, but recently there have been many reports of prolonged survival. I would like you to mention that point, see the following article of mine: Akutsu et al., 2020.

3. The author described that choroid plexus coagulation (CPC) is still rarely performed in developing countries. However, isn't it difficult in developing countries to manage VP shunts? There are reports recommending CPC over VP shunts for the treatment of hydrocephalus in developing countries. (Warf, 2005).

Taking all these things into account, this paper will require minor revisions before indexing.

Is the background of the case’s history and progression described in sufficient detail?
Yes
Are enough details provided of any physical examination and diagnostic tests, treatment given and outcomes?
Yes

Is sufficient discussion included of the importance of the findings and their relevance to future understanding of disease processes, diagnosis or treatment?
Yes

Is the case presented with sufficient detail to be useful for other practitioners?
Yes

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** Pediatric neurosurgery

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.
