Somatic-cell nuclear transfer is a cloning technique that enables the creation of a viable embryo from a donor adult to produce a genetically identical individual. This technique opens numerous potential possibilities for medicine and animal reproduction. However, several reports have documented cloning-related issues. Embryo and fetal losses remain significantly higher than in other techniques, and there is a high incidence of dystocia and hydrops, which decreases efficiency and increases costs. Animals delivered at term often exhibit a syndrome known as macrosomia and experience difficulties in adapting to life outside the uterus, and death is a common outcome. In the present study, 41 cloned calves that died in the neonatal period were subjected to gross and histopathological examination. Most important gross lesions were found in the liver (enlargement, congestion, yellowish color), kidneys (brownish color at surface and cut, and cysts), lungs (atelectasis, parenchymal consolidation, and secretions in bronchi and bronchioles), and heart (concentric and eccentric hypertrophy, hematic cysts, persistence of ductus arteriosus). Primary microscopic findings were seen in the liver, kidneys, and lungs from neonatal calves. In the liver, 85% of the animals exhibited hepatic degeneration. The presence of a brownish pigment within the cortical tubules of the kidneys was found in approximately 90% of the samples; the presence of this pigment has not been previously reported in cloned calves. In the lungs, a large number of animals exhibiting lesions characteristic of pneumonia (55%). These changes were the pivotal causes of death, mainly due to problems in adapting to life outside the uterus and opportunistic infections in the neonatal period. Further investigation focusing on pathological anatomical changes is necessary to map these abnormalities in cloned animals.

INDEX TERMS: Neonatology, cattle, calf, clone, necropsy, histopathology.
INTRODUCTION

Despite advances in the field of somatic cell nuclear transfer (SCNT), especially in cattle, market growth continues to stumble due to the low efficiency of the cloning technique in producing viable offspring. Only 0.5% to 5% of reconstructed embryos produce term animals; this low success rate results in losses at the embryonic, fetal, and perinatal stages (Palmieri et al. 2008, Bressan et al. 2015, Ibtisham et al. 2017). It has been estimated that up to 80% of losses occur in the second month due to problems in adaptation to the extrauterine environment and placentation (placentomegaly, congestion, and coloration amarelada), liver, renal, and cardiovascular system abnormalities (Barreto et al. 2009, Maiorka et al. 2015, Ao et al. 2019). Additionally, epigenetic reprogramming failures can lead to abnormal gene transcription and implantation mechanisms, initial post-implantation development, and fetal growth. Such failures lead to a higher rate of late fetal deaths, abnormalities observed in cloned calves (macrosomia, pulmonary hypertension, and neonatal asphyxia), and the highest rate of deaths in the neonatal period (Chavatte-Palmer et al. 2002, Lee et al. 2004, Kiefer et al. 2016).

It is believed that problems with placentation (placentomegaly, reduced vascularization of the chorioallantoic membrane, hypoplasia of the trophoblastic epithelium, and changes in the basement membrane) can result in significant losses during any gestational period (Lee et al. 2004, Palmieri et al. 2008, Barreto et al. 2009, Maiorka et al. 2015, Ao et al. 2019). Additionally, epigenetic reprogramming failures can lead to abnormal gene transcription and implantation mechanisms, initial post-implantation development, and fetal growth. Such failures lead to a higher rate of late fetal deaths, abnormalities observed in cloned calves (macrosomia, pulmonary hypertension, and neonatal asphyxia), and the highest rate of deaths in the neonatal period (Chavatte-Palmer et al. 2002, Lee et al. 2004, Kiefer et al. 2016).

Acute necropsy reports addressing cloned cattle are scarce, and those that are available only describe specific abnormalities (Birgel Junior et al. 2011, Maiorka et al. 2015). Moreover, the literature addressing the normal morphophysiology of newborn cattle is similarly scarce. Therefore, the present study aimed to describe pathological features of cloned (i.e., SCNT) calves that died in the neonatal period and to compare these with neonatal cattle of the same age group.

MATERIALS AND METHODS

Animals. This work was approved by the Ethics Committee on the Use of Animals (CEUA) of the Faculty of Agronomy and Veterinary Medicine of the University of Brasilia (Brasilia, Brazil), under process No. 2312/2013. Information regarding gestational length, calf age, and weight at death was collected. A total of 45 calves were evaluated, of which 41 were cloned that died in the neonatal period, and these were separated into two groups: Immediate Neonatal Group (ING), consisting of 25 cloned calves that died within the first 24 hours of life; and Late Neonatal Group (LNG), comprising 16 cloned calves that died between 2 and 28 days of life. All cloned calves are originated from Zebu breeds (subspecies Bos taurus indicus), from a commercial cloning company. The Control Group (CG) consisted of four male Girolando calves with age ranging from two to four days old. These animals were humanely euthanized using xylazine and thiopental (CFMV 2013) to compare pathological findings and verify whether such alterations are common to newborn cattle or are exclusive to cloned animals.

Necropsy and histological samples. The calves were subjected to necropsy immediately after spontaneous death (i.e., ING and LNG) or euthanasia (CG). Samples of the thoracic (heart and lungs) and abdominal (spleen, liver, and kidney) organs were fixed in 10% buffered formaldehyde and subsequently subjected to routine histological processing. Hematoxylin and eosin (HE) standard staining was initially used for screening, and the slides were evaluated under a light microscope. After initial screening, liver and kidney samples were stained with Schiff’s periodic acid (PAS). Kidney samples were also submitted to Hall staining to reveal bile pigments, Perls, for iron analysis; PAS staining for glycogen and lipofuscin; and Ziehl-Neelsen staining for lipofuscin. A comparative analysis of histological characteristics was performed among the three groups (i.e., ING, LNG, and CG).

RESULTS

The mean gestational age of the cloned calves was 290.5 days, being 289.9 days in ING and 291.5 days in LNG. The mean weight was 45.5 ± 10.4 kg, achieving 43.4 kg and 48.8 kg in ING and LNG, respectively (Table 1).

Main microscopic findings of the abdominal and thoracic organs are summarized in Table 2. Primary lesions were found in the liver (enlargement, congestion, yellowish color) (Fig.1A-B), kidneys (brownish color at surface and cut, and presence of cysts associated with cortical spinal rarefaction) (Fig.2A-B), lungs (atelectasis, parenchymal consolidation, and presence of varied secretions in bronchi and bronchioles) (Fig.3A-B), and heart (concentric and eccentric hypertrophy, presence of hematic cysts, and persistence of ductus arteriosus) (Fig.4A-B).

Main microscopic findings of the abdominal and thoracic organs are summarized in Table 3 and 4, respectively. In the liver, the most important changes included well-defined lobular pattern, virtually imperceptible sinusoids (both in 73% of cloned calves), closed distance between portal spaces (83%), cytoplasmic vacuolization of hepatocytes (85%) (Fig.1C-D), accumulation of glycogen (confirmed by PAS staining; 41%), centrlobular necrosis with fibrin deposition, and inflammatory infiltrate (6%). In the spleen,
Table 1. Minimum and maximum values, mean and standard deviation of gestation length (days), age (days), and weight (kg) of cloned calves that died in the neonatal period

| Group         | Gestation length (days) | Age (days) | Weight (kg) |
|---------------|-------------------------|------------|-------------|
|               | Min | Max  | Mean ± SD | Min | Max  | Mean ± SD | Min | Max  | Mean ± SD |
| ING (n=25)    | 272 | 308  | 289.9 ± 8.69 | 0   | 2    | 0.75 ± 0.76 | 23  | 59   | 43.4 ± 9.92 |

Table 2. Gross pathology findings in cloned and control calves that died in the neonatal period

| Organ                      | ING | LNG |
|----------------------------|-----|-----|
| Liver                      | Fibrosis, Necrosis, Hepatomegaly, Irregular surface, Opaque thickened capsule, Subcapsular hematoma, Pale or yellowish coloring on the surface and cut, Reddish spots on the surface and cut, Congestion | Hepatomegaly, Pale or yellowish coloring on the surface and cut, Congestion | Brownish color, on the surface and cut, Regular edges, Smooth and shiny surface |
| Spleen                     | Thickened and whitish capsule, Mild splenomegaly | White pulp hyperplasia | No lesion |
| Kidneys                    | Hydronephrosis, Congestion, Fat accumulation at perirenal, pelvis, gobleets, and papillae, Translucent gelatinous material in pelvis, Blackish brown color on the surface and cut, Whitish to yellowish streaks in cortex and medulla, Cystic dilations in the region of renal or medullary calyces, with associated medullary cortication | Congestion, Friable, Fat accumulation at perirenal, pelvis, gobleets, and papillae, Blackish brown color on the surface and cut, Whitish to yellowish streaks in cortex and medulla, Cystic dilations in the region of renal or medullary calyces, with associated medullary cortication | Brownish color on the surface (cortical and pinkish medullary region), Moderate amount of perirenal fat reaching the pelvis |
| Respiratory system         | Pulmonary edema, Congestion, Aspirative pneumonia, Tracheal hemorrhage, Pulmonary emphysema, Areas of atelecasis, Consolidation areas, Irregular surface, Variable amount of whitish foam and liquid from the beginning of the trachea to secondary bronchi, Yellowish or greenish material from lumpy to pasty consistency, Petechiae and red striations in the larynx, trachea, and bronchi | Pulmonary edema, Pneumonia, Consolidation areas, Irregular surface, Moderate amount of whitish, yellowish or greenish catarrhal material in bronchi and bronchioles | Pink coloring, Uniform appearance, Fully expanded |
| Cardiovascular system      | Cardiomegaly, Umbilical veins and caudal vena cava rupture, Fat accumulation in epicardium, Identifiable oval foramen and ductus arteriosus, Persistence of the ductus arteriosus, Hematic cysts adhered to the endocardium (mainly in the atrioventricular valves), Bright, slightly firm nodules adhered to atrioventricular valves, suggestive of endocardiosis, Concentric hypertrophy of the right ventricle (RV) and interventricular septum, and more rarely affecting the left ventricle (LV), RV eccentric hypertrophy | Cardiomegaly, Pericardial pectechiae, Valvar hemorrhage, Fibrillary adhesions between pericardial sac and epicardium, Hydropericardium, Hematic cysts adhered to the endocardium (mainly in the atrioventricular valves), Fat accumulation in epicardium, Iliac arteries thrombosis, Fat accumulation in epicardium, (interventricular septum and base), RV and inter-ventricular septum free wall slightly thickened, Oval foramen and arterial duct identifiable, but non functional | Fat accumulation in epicardium, (interventricular septum and base) |
| Other findings             | Hemothorax, Macrosomia, Enteritis, Omphalitis, Fetal monster (Dexter) | Peritonitis, Omphalitis, Macrosomia, Enteritis, Ruminal drinker, Abomasum rupture, Bladder rupture | No lesion |

ING = Immediate neonatal group, LNG = late neonatal group.
Pathological features of cloned calves that died in the neonatal period

The most common finding was reduction in white pulp (48% of cases), evidenced by cellular rarefaction in lymphoid follicles. The kidneys exhibited smaller, hypercellular, and closer glomeruli (glomeruli with an embryonic aspect; 88%) and brownish granules within the cortical tubule cells (90%) (Fig. 2C). After applying special stains (Hall, Perls, PAS, and Ziehl-Neelsen), only the lipofuscin stain labeled the observed granules, but not as characteristically as control fragments (Fig. 2D). Inflammatory cell infiltration (55% of cloned calves) (Fig. 3C-D), atelectasis (45%), and pulmonary edema (35%) (Fig. 3E) were the most common findings in the lungs. A yellowish amorphous substance (suggestive of meconium aspiration; 28% of cases) (Fig. 3C), and pinkish amorphous substance (suggestive of milk aspiration; 18%) were also observed, most often associated with severe inflammatory infiltrate, indicating aspiration pneumonia. In the heart, there was a slight to moderate vacuolization of cardiac fibers (28%), which appeared as round vacuoles that left the cell swollen (Fig. 4C). Greater spacing between fiber bundles was also observed (45%). In the CG, the same spacing of cardiac fiber bundles was observed, but at lower intensity (Fig. 4D).

DISCUSSION

Dead cloned calves in the present study exhibited pathological changes in several organs. Main changes observed were the presence of a brownish pigment inside the renal cortical tubules (approximately 90% of cases), liver degeneration (85% of evaluated samples), and lesions characteristic of pneumonia (55% of animals). In fact, several reports have described congenital and acquired changes in cloned animals (Garry et al. 1996, Taneja et al. 2001, Rhind et al. 2003, Panarace et al. 2007, Santos et al. 2010, Maiorka et al. 2015). On the other hand, some studies did not find any alteration(s) at necropsy of cloned animals that died in the neonatal period (Wilmut et al. 1997, Kato et al. 1998, Lee et al. 2004). This absence of changes may be related to acute anoxia, which may explain the apparent lack of findings in many necropsies (Mee 2011). Additionally, neonatal deaths are often associated with respiratory problems, especially in depressed and long-standing calves (Wilson et al. 1995, Garry et al. 1996). Respiratory distress is believed to be the most common sign in calves that died without any other abnormalities (Panarace et al. 2007).

In the present study, the livers of cloned calves exhibited an irregular surface and a thickened and opaque capsule, which have also been previously described (Hill et al. 1999).

Fig. 1. Changes observed in the liver of cloned and control neonates. (A) Irregular liver surface, cloned calf. (B) Normal liver, control animal. (C) Marked hepatocyte vacuolization, cloned bovine. HE, obj. 40x. (D) Discrete bovine hepatocyte vacuolization, control calf. HE, obj. 40x.
Subcapsular hematoma was observed in only one calf; however, there was no apparent explanation for its appearance and no correlation with other specific changes was found. Congestion and hepatic hemorrhage were observed in four animals under microscopy. The occurrence of hepatic congestion in cloned bovine neonates has been previously reported (Santos et al. 2010, Maiorka et al. 2015), indicating that this is a common finding in these animals. In control calves, the occurrence of hepatic congestion can be attributed to the agent used for euthanasia (thiopental) (Thomson 1998). The observation of hepatomegaly and hepatic steatosis, together with microscopic findings, revealed that vacuolated hepatocytes to varying degrees in cloned calves, however, more accentuated in ING animals, can be interpreted as fatty degeneration (due to the morphology of the vacuoles and macroscopic findings). Fatty degeneration has been attributed to the contribution of fat greater than the metabolism or the reduction in synthesis of proteins and lipoproteins involved in the transport of lipids out of the cell. It occurs in animals in starvation or severe food restriction, and also in other situations such as poisonings, ketosis in ruminants, and those with diabetes mellitus (Thomson 1998).

In the CG, some degree of hepatic fatty degeneration and areas of central-lobular necrosis were also observed; however, the intensity of injury was less severe compared with cloned calves. Fatty degeneration, enhancement of the lobular pattern, and central-lobular necrosis can be associated with hypoxia and death (Thomson 1998). In cloned sheep fetuses, hepatic degeneration suggests that the cause of such abnormalities is due to the lack of placental nutrition (De Sousa et al. 2001), as observed in several cloned calves, mainly from the ING. These changes were prominent in clones of advanced age, which may indicate liver regeneration in response to enteral feeding and independence from placental nutrition. The presence of hepatocyte vacuolization in the liver of bovine fetuses (Okano et al. 2003) and bovine neonates from in vitro fertilization (Prestes et al. 2009) has also been reported. It can be inferred, therefore, that some degree of hepatocyte vacuolization is normal in newborn animals. However, moderate to severe degeneration(s) can be interpreted as abnormal findings.

Okano et al. (2003) attributed hepatic vacuolization to the accumulation of glycogen in aborted animals, confirmed by PAS staining. Although hepatic glycogen was found in some animals, which is considered to be normal in mild to moderate amounts (Thomson 1998), a pathological finding (i.e., significant amount)
was present in 8 of 41 cloned and 1 of 4 control calves. It was found that changes in DNA methylation patterns in cloned cattle can interfere with hepatic metabolism, leading to changes in glycogen storage and fatty acid composition (Kiefer et al. 2016). It is mainly due to changes in genes, such as TCF7L2, in which polymorphisms have been associated with the development of type 2 diabetes. In fact, in the present investigation and several previous studies, moderate to severe fat deposition was observed in various tissues (Chavatte-Palmer et al. 2002, Santos et al. 2010, Maiorka et al. 2015).

In the spleen of cloned animals, macroscopic findings included mild splenomegaly and thickening of the capsule. Regarding

microscopic findings, congestion was observed because it is related to congestive heart failure, liver cirrhosis, or other causes of increased retrograde pressure (Thomson 1998). This fact is consistent with that observed in the present study, which sometimes revealed thickening of the right ventricle and liver degeneration. Hemorrhage and hemosiderosis are likely due to prolonged congestion (Thomson 1998). Little evidence of white pulp was also observed in the spleens of cloned animals; and previous reports showed marked follicular rarefaction in a 50-day-old calf (Renard et al. 1999), in addition to white pulp hypoplasia and changes in other lymphoid organs in cloned calves (Santos et al. 2010).

In the kidneys of cloned calves, brown granules, proliferation of connective tissue, fibrosis, tubular degeneration, necrosis, and lymphocytic and plasmacytic infiltrates were observed. Several renal lesions have been reported in cloned animals, including cystic formations associated with dilated tubules (Santos et al. 2010), and severe bilateral hydronephrosis associated with obstructive lesions in the urinary system (Wells et al. 1997, Rhind et al. 2003). The presence of brownish granules inside the cells of the cortical and medullary tubules was observed only in the kidneys of cloned calves. It was not possible to accurately identify this pigmentation; however, it is known that the observed pigment does not originate from the accumulation of bile pigments, iron, hemosiderin or glycogen, as no characteristic coloring was evident with the techniques used (i.e., Hall, Perls, and PAS, respectively). Okano et al. (2003) described vacuolization of the renal tubular epithelium in aborted calves that exhibited positive staining using the PAS method. In the present study, PAS staining did not characterize the granules observed in the tubular epithelium. However, there was positive staining in the collecting tubules of the renal cortex using this method. The granules observed exhibited many characteristics similar to those of lipofuscin; however, due to the techniques used in this study, such confirmation was not possible. Although staining for lipofuscin identified the granules, it was not with the expected intensity. Lipofuscin can accumulate within epithelial cells of the renal tubules in older cattle in the form of fine golden granules (Zachary & McGavin 2012). Macroscopically, lipofuscin is evident as brown streaks in the renal cortex, similar to the macroscopic findings reported here. Akagi et al. (2003) described a kidney injury as a deposit of lipofuscin in the tubular epithelium of a cloned calf that died at 13 days of age. It is believed that the presence of such granules warrant further analysis in attempts to determine the origin of the pigment and its relationship with observed renal changes.

Fig. 4. Changes observed in the heart of cloned neonates and controls. (A) Cardiac muscle hypertrophy, cloned calf. (B) Normal organ characteristic, control calf. (C) Vacuolization of cardiomyocytes, cloned calf. HE, obj.40x. (D) Note less vacuolization and spacing of cardiomyocytes, control calf. HE, obj.40x.
The lungs were the organs with the highest number of alterations (virtually all cloned calves exhibited some finding in the lungs). In the ING, the most common finding was atelectasis, which is consistent with previous studies (Santos et al. 2010, Maiorka et al. 2015). Atelectasis is characterized by incomplete expansion of the alveoli and can be caused by several factors, including neonatal asphyxia, pulmonary hypertension, and aspiration of amniotic fluid or meconium (Dungworth 1993). The occurrence of atelectasis was found to be determinant of the animals’ survival beyond the immediate

ING = immediate neonatal group, LNG = late neonatal group.
neonatal period. The atelectasis observed in cloned animals could often be associated with pulmonary immaturity and deficiency in surfactant production (Preztes et al. 2009), which leads to chronic pulmonary hypertension. Meconium aspiration observed in several ING animals, and also previously reported in cloned calves (Maiorka et al. 2015), is another factor that may have contributed to the observed atelectasis. Meconium reacts with phospholipids present in the surfactant, which causes failures in this layer and, thus, leads to atelectasis (Bleul 2009). In LNG animals, the most striking finding in the lungs was pneumonia. Many animals that died in the late neonatal period presented with aspiration pneumonia (meconium or milk aspiration), diffuse peritonitis due to ruptured abomasal ulcer(s), umbilical conditions, and passive immunity transfer failure. Therefore, the occurrence of such pulmonary changes is often secondary to other conditions. In septicemia, it is common detachment of septic emboli, which may migrate to the lungs, causing severe pneumonia (Dungworth 1993). Other changes observed in the lungs, such as fibrin deposition, proliferation of type II pneumocytes, thickening of the septum, hyperplasia of type I pneumocytes, proliferation of connective tissue, and necrosis, are common findings in pneumonia and have also been previously reported (Hill et al. 2000, Li et al. 2005, Santos et al. 2010, Maiorka et al. 2015).

In the heart, the fibrillar adhesions observed between the pericardial sac and the epicardium were consistent with an initial condition of fibrinous pericarditis, which, in neonates, may be due to coliform infection acquired by umbilical route (Robinson & Maxie 1993). Lesions suggestive of endocardiosis were observed only in the hearts of cloned animals. Endocardiosis refers to a proliferation of loose connective tissue in the valve(s), accompanied by deposition of glycosaminoglycan, with concomitant collagen degeneration in the fibrous valve (Robinson & Maxie 1993). Lesions related to endocardiosis have not yet been described in cloned animals. A case of hydropericardium was also identified, a lesion previously reported in cloned calves (Maiorka et al. 2015). This change may be related to congestive heart failure; other common causes of hydropericardium include anasarca, emaciating diseases, and neoplasms (Robinson & Maxie 1993). Hypertrophy of the right ventricle, previously described in cloned animals (Garry et al. 1996, Hill et al. 1999, Rhind et al. 2003, Santos et al. 2010), is attributed to congenital pulmonary hypertension (Hill et al. 1999, Rhind et al. 2003). An additional finding in the hearts of cloned calves in the present study was the persistence of foramen ovale and ductus arteriosus, which was also reported (Maiorka et al. 2015). Hematic cysts are generally not attributed to any specific lesion. However, in

ING = immediate neonatal group, LNG = late neonatal group.
the present study, they were observed only in cloned calves. As frequently observed in cloned calves (Santos et al. 2010, Maiorka et al. 2015), especially in animals with heart disease, it is likely that cloned animals develop heart disease with the formation of hematic cysts and persistence of the foramen ovale and ductus arteriosus.

Vacuolization of cardiomyocytes was observed in the present study. However, it was not possible to identify the origin of the vacuoles due to the preparation/storage method of the sample material, which was stored in formaldehyde, thus making specific staining (i.e., Sudan staining) impossible, which requires the material to be frozen. It is probably related to fatty degeneration, similar to the degeneration seen in the liver (Thomson 1998), and analogous to cardiomy degeneration in animals from in vitro fertilization (Presstes et al. 2009). The greater spacing of cardiac fibers was an alteration observed in cloned animals to a higher degree than in the CG and is often associated with myocyte vacuolization. The implications of this greater spacing on the health of cloned animals remain unclear, and such reports were not found in the literature.

The increased mortality of newborn cloned calves might be due to an abnormal immunity, increasing the susceptibility to infections. In health calves, the immune system’s development is complete at birth, although it is still immature (Cortese 2003). In fact, about half of the cloned calves evaluated here showed reduced spleen white pulp. This fact may have increased the risk for pneumonia and umbilical infection. Additionally, most cloned calves present failures during adaptation to extrauterine life, being commonly observed prostration, lethargy, difficulties in adapting to extrauterine life, being commonly observed prostration, lethargy, absence of the suck reflex and meconium elimination (Birgel Junior et al. 2011). Furthermore, vascular disorders were reported in cloned calves (Maiorka et al. 2015), which was also evident herein. Another reason contributing for the high mortality rate in cloned animals in the present study is impaired kidney function. Most common lesions included presence of brown granules (probably lipofuscin), proliferation of connective tissue, fibrosis, tubular degeneration, necrosis, and lymphocytic and plasmacytic infiltrates.

CONCLUSIONS

The main causes of death among cloned calves that died in the immediate neonatal period were liver damage, characterized mainly by marked hepatic degeneration, and difficulties in adapting to extrauterine life, clinically demonstrated as respiratory difficulty and pathologically as pulmonary disease (more specifically atelectasis), which circumstantially contributed to the death of these animals.

In calves that experienced late neonatal death (i.e., LNG), the most notable finding was severe pneumonia, which in many cases was secondary to other concurrent diseases. It is believed that this type of pneumonia is a significant contributor to death.

Findings in the kidneys of cloned animals warrant further investigations to determine the origin of the granules inside the cortical tubules and their relationship with other abnormalities in these animals. These changes may be caused by changes in DNA methylation pattern(s), resulting in epigenetic changes in animal metabolism.
