Abstract

Randomized smoothing has been successfully applied to classification tasks on high-dimensional inputs, such as images, to obtain models that are provably robust against adversarial perturbations of the input. We extend this technique to produce provable robustness for functions that map inputs into an arbitrary metric space rather than discrete classes. Such functions are used in many machine learning problems like image reconstruction, dimensionality reduction, facial recognition, etc. Our robustness certificates guarantee that the change in the output of the smoothed model as measured by the distance metric remains small for any norm-bounded perturbation of the input. We can certify robustness under a variety of different output metrics, such as total variation distance, Jaccard distance, perceptual metrics, etc. In our experiments, we apply our procedure to create certifiably robust models with disparate output spaces – from sets to images – and show that it yields meaningful certificates without significantly degrading the performance of the base model. The code for our experiments is available at: https://github.com/aounon/center-smoothing.

1 Introduction

The study of adversarial robustness in machine learning has gained a lot of attention ever since deep neural networks (DNNs) have been demonstrated to be vulnerable to adversarial attacks. They are tiny perturbations of the input that can completely alter a model’s predictions [48, 38, 17, 27]. These maliciously chosen perturbations can significantly degrade the performance of a model, like an image classifier, and make it output almost any class that the attacker wants. However, these attacks are not just limited to classification problems. Recently, they have also been shown to exist for DNN-based models with many different kinds of outputs like images, probability distributions, sets, etc. For instance, facial recognition systems can be deceived to evade detection, impersonate authorized individuals and even render them completely ineffective [50, 47, 14]. Image reconstruction models have been targeted to introduce unwanted artefacts or miss important details, such as tumors in MRI scans, through adversarial inputs [1, 42, 6, 7]. Similarly, super-resolution systems can be made to generate distorted images that can in turn deteriorate the performance of subsequent tasks that rely on the high-resolution outputs [9, 54]. Deep neural network based policies in reinforcement learning problems also have been shown to succumb to imperceptible perturbations in the state observations [15, 22, 2, 40]. Such widespread presence of adversarial attacks is concerning as it threatens the use of deep neural networks in critical systems, such as facial recognition, self-driving vehicles, medical diagnosis, etc., where safety, security and reliability are of utmost importance.

Adversarial defenses have mostly focused on classification tasks [26, 4, 20, 12, 36, 19, 16]. Provable defenses based on convex-relaxation [52, 41, 43, 8, 46], interval-bound propagation [18, 21, 15, 39] and randomized smoothing [10, 28, 54, 53] that guarantee that the predicted class will remain the same in a certified region around the input point have also been studied. Among these approaches
randomized smoothing scales up to high-dimensional inputs, such as images, and does not need access to or make assumptions about the underlying model. The robustness certificates produced are probabilistic, meaning that they hold with high probability. First studied by Cohen et al.\(^\text{10}\), smoothing methods sample a set of points in a Gaussian cloud around an input, and aggregate the predictions of the classifier on these points to generate the final output.

While accuracy is the standard quality measure for classification, more complex tasks may require other quality metrics like total variation for images, intersection over union for object localization, earth-mover distance for distributions, etc. In general, networks can be cast as functions of the type \(f : \mathbb{R}^k \to (M, d)\) which map a \(k\) dimensional real-valued space into a metric space \(M\) with distance function \(d : M \times M \to \mathbb{R}_{\geq 0}\). In this work, we extend randomized smoothing to obtain provable robustness for functions that map into arbitrary metric spaces. We generate a robust version \(\bar{f}\) such that the change in its output, as measured by \(d\), is small for a small change in its input. More formally, given an input \(x\) and an \(\ell_2\)-perturbation size \(\epsilon_1\), we produce a value \(\epsilon_2\) with the guarantee that, with high probability,

\[
\forall x' \text{ s.t. } ||x - x'||_2 \leq \epsilon_1, \ d(\bar{f}(x), \bar{f}(x')) \leq \epsilon_2.
\]

Our contributions: We develop center smoothing, a technique to make functions like \(f\) provably robust against adversarial attacks. For a given input \(x\), center smoothing samples a collection of points in the neighborhood of \(x\) using a Gaussian smoothing distribution, computes the function \(f\) on each of these points and returns the center of the smallest ball enclosing at least half the points in the output space (see figure 1). Computing the minimum enclosing ball in the output space is equivalent to solving the 1-center problem with outliers (hence the name of our procedure), which is an NP-complete problem for a general metric\(^\text{44}\). We approximate it by computing the point that has the smallest median distance to all the other points in the sample. We show that the output of the smoothed function is robust to input perturbations of bounded \(\ell_2\)-size. Although we defined the output space as a metric, our proofs only require the symmetry property and triangle inequality to hold. Thus, center smoothing can also be applied to pseudometric distances that need not satisfy the identity of indiscernibles. Many distances defined for images, such as total variation, cosine distance, perceptual distances, etc., fall under this category. Center smoothing steps outside the world of \(\ell_p\) metrics, and certifies robustness in metrics like IoU/Jaccard distance for object localization, and total-variation, which is a good measure of perceptual similarity for images. In our experiments, we show that this method can produce meaningful certificates for a wide variety of output metrics without significantly compromising the quality of the base model.

Related Work: Randomized smoothing has been extensively studied for classification problems to obtain provably robust models against many different \(\ell_p\)\(^\text{10, 28, 43, 49, 35, 33, 29, 32}\) and non-\(\ell_p\)\(^\text{30, 31}\) threat models. Beyond classification tasks, it has also been used for certifying the median output of regression models\(^\text{53}\) and the expected softmax scores of neural networks\(^\text{25}\). Smoothing a vector-valued function by taking the mean of the output vectors has been shown to have a bounded Lipschitz constant when both input and output spaces are \(\ell_2\)-metrics\(^\text{51}\). However, existing methods do not generate the type of certificates described above for general distance metrics. Center smoothing takes the distance function of the output space into account for generating the robust output and thus results in a more natural smoothing procedure for the specific distance metric.

2 Preliminaries and Notations

Given a function \(f : \mathbb{R}^k \to (M, d)\) and a distribution \(D\) over the input space \(\mathbb{R}^k\), let \(f(D)\) denote the probability distribution of the output of \(f\) in \(M\) when the input is drawn from \(D\). For a point \(x \in \mathbb{R}^k\), let \(x + \mathcal{P}\) denote the probability distribution of the points \(x + \delta\) where \(\delta\) is a smoothing noise drawn from a distribution \(\mathcal{P}\) over \(\mathbb{R}^k\) and let \(X\) be the random variable for \(x + \mathcal{P}\). For elements in \(M\), define \(B(z, r) = \{z' \mid d(z, z') \leq r\}\) as a ball of radius \(r\) centered at \(z\). Define a smoothed version of \(f\) under \(\mathcal{P}\) as the center of the ball with the smallest radius in \(M\) that encloses at least half of the probability mass of \(f(x + \mathcal{P})\), i.e.,

\[
\bar{f}_\mathcal{P}(x) = \arg \min_r \mathbb{P}[f(X) \in B(z, r)] \geq \frac{1}{2},
\]
We use this bound to generate robustness certificates for center smoothing. We identify a ball $B$ as defined in section 2, the output of $f(x) = \arg\max_{c \in \mathcal{Y}} \Pr[h(x + \delta) = c]$, where $\mathcal{Y}$ is a set of classes, is certifiably robust to small perturbations in the input. Their certificate relied on the fact that, if the probability of sampling from the top class at $x$ under the smoothing distribution is $p$, then for an $\ell_2$ perturbation of size at most $\epsilon$, the probability of the top class is guaranteed to be at least

$$p_{\epsilon} = \Phi(\Phi^{-1}(p) - \epsilon / \sigma),$$

where $\Phi$ is the CDF of the standard normal distribution $N(0, 1)$. This bound applies to any \{0, 1\}-function over the input space $\mathbb{R}^k$, i.e., if $\Pr[h(x) = 1] = p$, then for any $\epsilon$-size perturbation $x'$, $\Pr[h(x') = 1] \geq p_{\epsilon}$.

We use this bound to generate robustness certificates for center smoothing. We identify a ball $B(\bar{f}(x), R)$ of radius $R$ enclosing a very high probability mass of the output distribution. One can define a function that outputs one if $f$ maps a point to inside $B(\bar{f}(x), R)$ and zero otherwise. The bound in (1) gives us a region in the input space such that for any point inside it, at least half of the mass of the output distribution is enclosed in $B(\bar{f}(x), R)$. We show in section 3 that the output of the smoothed function for a perturbed input is guaranteed to be within a constant factor of $R$ from the output of the original input.

3 Center Smoothing

As defined in section 2, the output of $\bar{f}$ is the center of the smallest ball in the output space that encloses at least half the probability mass of the $f(x + P)$. Thus, in order to significantly change the output, an adversary has to find a perturbation such that a majority of the neighboring points map far away from $\bar{f}(x)$. However, for a function that is roughly accurate on most points around $x$, a small perturbation in the input cannot change the output of the smoothed function by much, thereby making it robust.

For an $\ell_2$ perturbation size of $\epsilon_1$ of an input point $x$, let $R$ be the radius of a ball around $\bar{f}(x)$ that encloses more than half the probability mass of $f(x' + P)$ for all $x'$ satisfying $\|x - x'\|_2 \leq \epsilon_1$, i.e.,

$$\forall x' \text{ s.t. } \|x - x'\|_2 \leq \epsilon_1, \quad \Pr[f(X') \in B(\bar{f}(x), R)] > \frac{1}{2},$$

where $X \sim x' + P$. Basically, $R$ is the radius of a ball around $\bar{f}(x)$ that contains at least half the probability mass of $f(x' + P)$ for any $\epsilon_1$-size perturbation $x'$ of $x$. Then, we have the following robustness guarantee on $\bar{f}$:

**Theorem 1.** For all $x'$ such that $\|x - x'\|_2 \leq \epsilon_1$,

$$d(\bar{f}(x), \bar{f}(x')) \leq 2R.$$

**Proof.** Consider the balls $B(\bar{f}(x), r^*(x'))$ and $B(\bar{f}(x), R)$ (see figure 2). From the definition of $r^*(x')$ and $R$, we know that the sum of the probability masses of $f(x' + P)$ enclosed by the two balls must be strictly greater than one. Thus, they must have an element $y$ in common. Since $d$ satisfies the triangle inequality, we have:

$$d(\bar{f}(x), \bar{f}(x')) \leq d(\bar{f}(x), y) + d(y, \bar{f}(x')) \leq R + r^*(x').$$
Since, the ball $B(\bar{f}(x), R)$ encloses more than half of the probability mass of $f(x + \mathcal{P})$, the minimum ball with at least half the probability mass cannot have a radius greater than $R$, i.e., $r^*(x') \leq R$. Therefore, $d(f(x), f(x')) \leq 2R$. □

The above result, in theory, gives us a smoothed version of $f$ with a provable guarantee of robustness. However, in practice, it may not be feasible to obtain $\bar{f}$ just from samples of $f(x + \mathcal{P})$. Instead, we will use some procedure that approximates the smoothed output with high probability. For some $\Delta \in [0, 1/2]$, let $\hat{r}(x, \Delta)$ be the radius of the smallest ball that encloses at least $1/2 + \Delta$ probability mass of $f(x + \mathcal{P})$, i.e.,

$$\hat{r}(x, \Delta) = \min \_{r \text{ s.t.} \mathbb{P}[f(X) \in B(z', r)] \geq \frac{1}{2} + \Delta} r.$$  

Now define a probabilistic approximation $\hat{f}(x)$ of the smoothed function $\bar{f}$ to be a point $z \in M$, which with probability at least $1 - \alpha_1$ (for $\alpha_1 \in [0, 1]$), encloses at least $1/2 - \Delta$ probability mass of $f(x + \mathcal{P})$ within a ball of radius $\hat{r}(x, \Delta)$. Formally, $\hat{f}(x)$ is a point $z \in M$, such that, with at least $1 - \alpha_1$ probability,

$$\mathbb{P}[f(X) \in B(z, \hat{r}(x, \Delta))] \geq \frac{1}{2} - \Delta.$$  

Defining $\hat{R}$ to be the radius of a ball centered at $\hat{f}(x)$ that satisfies:

$$\forall x' \text{ s.t. } \|x - x'\|_2 \leq \epsilon_1, \mathbb{P}[f(X') \in B(\hat{f}(x), \hat{R})] > \frac{1}{2} + \Delta, \quad (3)$$

we can write a probabilistic version of theorem [1].

**Theorem 2.** With probability at least $1 - \alpha_1$,

$$\forall x' \text{ s.t. } \|x - x'\|_2 \leq \epsilon_1, \ d(\hat{f}(x), \hat{f}(x')) \leq 2\hat{R},$$

The proof of this theorem is in the appendix, and logically parallels the proof of theorem [1].

### 3.1 Computing $\hat{f}$

For an input $x$ and a given value of $\Delta$, sample $n$ points independently from a Gaussian cloud $x + \mathcal{N}(0, \sigma^2 I)$ around the point $x$ and compute the function $f$ on each of these points. Let $Z = \{z_1, z_2, \ldots, z_n\}$ be the set of $n$ samples of $f(x + \mathcal{N}(0, \sigma^2 I))$ produced in the output space. Compute the minimum enclosing ball $B(z, r)$ that contains at least half of the points in $Z$. The following lemma bounds the radius $r$ of this ball by the radius of the smallest ball enclosing at least $1/2 + \Delta$ probability mass of the output distribution (proof in appendix).

**Lemma 1.** With probability at least $1 - e^{-2n\Delta^2}$,

$$r \leq \hat{r}(x, \Delta_1).$$

Now, sample a fresh batch of $n$ random points and compute the $1 - e^{-2n\Delta^2}$ probability Hoeffding lower-bound $p_{\Delta_1}$ of the probability mass enclosed inside $B(z, r)$ by counting the number of points that fall inside the ball, i.e., calculate the $p_{\Delta_1}$ for which, with probability at least $1 - e^{-2n\Delta^2}$,

$$\mathbb{P}[f(X) \in B(z, r)] \geq p_{\Delta_1}.$$  

Let $\Delta_2 = 1/2 - p_{\Delta_1}$. If $\max(\Delta_1, \Delta_2) \leq \Delta$, the point $z$ satisfies the conditions in the definition of $\hat{f}$, with at least $1 - 2e^{-2n\Delta^2}$ probability. If $\max(\Delta_1, \Delta_2) > \Delta$, discard the computed center $z$ and abstain. In our experiments, we select $\Delta_1, n$ and $\alpha_1$ appropriately so that the above process succeeds easily.

Computing the minimum enclosing ball $B(z, r)$ exactly can be computationally challenging, as for certain norms, it is known to be NP-complete [44]. Instead, we approximate it by computing a ball $\beta$-MEB($Z$, 1/2) that contains at least half the points in $Z$, but has a radius that is within $\beta r$ units of the optimal radius, for a constant $\beta$. We modify theorem [1] to account for this approximation (see appendix for proof).
Algorithm 1 Smooth

**Input:** $x \in \mathbb{R}^k, \sigma, \Delta, \alpha_1$.

**Output:** $z \in M$.

Set $Z = \{z_i\}_{i=1}^m$ s.t. $z_i \sim f(x + N(0, \sigma^2 I))$.

Set $\Delta_1 = \sqrt{\ln(2/\alpha_1)}/2m$.

Compute $z = \beta$-MEB($Z, 1/2$).

Re-sample $Z$.

Compute $p_{\Delta_1}$.

Set $\Delta_2 = 1/2 - p_{\Delta_1}$.

If $\Delta < \max(\Delta_1, \Delta_2)$, discard $z$ and abstain.

Algorithm 2 Certify

**Input:** $x \in \mathbb{R}^k, \epsilon_1, \sigma, \Delta, \alpha_1, \alpha_2$.

**Output:** $e_2 \in \mathbb{R}$.

Compute $\hat{f}(x)$ using algorithm 1

Set $Z = \{z_i\}_{i=1}^m$ s.t. $z_i \sim f(x + N(0, \sigma^2 I))$.

Compute $\hat{R} = \{d(\hat{f}(x), f(z_i)) | z_i \in Z\}$.

Set $p = \Phi(\Phi^{-1}(1/2 + \Delta) + \epsilon_1/\sigma)$.

Set $q = p + \sqrt{\ln(1/\alpha_2)/2m}$.

Set $\hat{R} = q$-th quantile of $\hat{R}$.

Set $e_2 = (1 + \beta)\hat{R}$.

**Theorem 3.** With probability at least $1 - \alpha_1$,

$$\forall x', \text{s.t. } \|x - x'\|_2 \leq \epsilon_1, \ d(\hat{f}(x), \hat{f}(x')) \leq (1 + \beta)\hat{R}$$

where $\alpha_1 = 2e^{-2\alpha_2\Delta^2}$.

We use a simple approximation that works for all metrics and achieves an approximation factor of two, producing a certified radius of $3\hat{R}$. It computes a point from the set $Z$, instead of a general point in $M$, that has the minimum median distance from all the points in the set (including itself). This can be achieved using $O(n^2)$ pair-wise distance computations. To see how the factor 2-approximation is achieved, consider the optimal ball with radius $r$. Each pair of points is at most $2r$ distance from each other. Thus, a ball with radius $2r$, centered at one of these points will cover every other point in the optimal ball. Better approximations can be obtained for specific norms, e.g., there exists a $(1 + \epsilon)$-approximation algorithm for the $\ell_2$ norm [5]. For graph distances, the optimal radius can be computed exactly using the above algorithm. The smoothing procedure is outlined in algorithm 1.

**3.2 Certifying $\hat{f}$**

Given an input $x$, compute $\hat{f}(x)$ as described above. Now, we need to compute a radius $\hat{R}$ that satisfies condition 1. As per bound 1 in order to maintain a probability mass of at least $1/2 + \Delta$ for any $\epsilon_1$-size perturbation of $x$, the ball $B(\hat{f}(x), \hat{R})$ must enclose at least

$$p = \Phi \left( \Phi^{-1} \left( \frac{1}{2} + \Delta \right) + \frac{\epsilon_1}{\sigma} \right)$$

probability mass of $f(x + \mathcal{P})$. Again, just as in the case of estimating $\bar{f}$, we may only compute $\hat{R}$ from a finite number of samples $\hat{m}$ of the distribution $f(x + \mathcal{P})$. For each sample $z_i \sim x + \mathcal{P}$, we compute the distance $d(\hat{f}(x), f(z_i))$ and set $\hat{R}$ to be the $q$-th quantile $\hat{R}_q$ of these distances for a $q$ that is slightly greater than $p$ (see equation 5 below). The $q$-th quantile $\hat{R}_q$ is a value larger than at least $q$ fraction of the samples. We set $q$ as,

$$q = p + \sqrt{\frac{\ln(1/\alpha_2)}{2\hat{m}}}$$

for some small $\alpha_2 \in [0, 1]$. This guarantees that, with high probability, the ball $B(\hat{f}(x), \hat{R}_q)$ encloses at least $p$ fraction of the probability mass of $f(x + \mathcal{P})$. We prove the following lemma by bounding the cumulative distribution function of the distances of $f(z_i)$s from $f(x)$ using the Dvoretzky–Kiefer–Wolfowitz inequality.

**Lemma 2.** With probability $1 - \alpha_2$,

$$\mathbb{P} \left[ f(X) \in B(\hat{f}(x), \hat{R}_q) \right] > p$$

Combining with theorem 5 we have the final certificate:

$$\forall x' \text{ s.t. } \|x - x'\|_2 \leq \epsilon_1, \ d(\hat{f}(x), \hat{f}(x')) \leq (1 + \beta)\hat{R},$$
with probability at least $1 - \alpha$, for $\alpha = \alpha_1 + \alpha_2$. In our experiments, we set $\alpha_1 = \alpha_2 = 0.005$ to achieve an overall success probability of $1 - \alpha = 0.99$, and calculate the required $\Delta_1, \Delta_2$ and $q$ values accordingly. We set $\Delta$ to be as small as possible without violating $\max(\Delta_1, \Delta_2) \leq \Delta$ too often. We use a $\beta = 2$-approximation for computing the minimum enclosing ball in the smoothing step. Algorithm 2 provides the pseudocode for the certification procedure.

4 Relaxing Metric Requirements

Although we defined our procedure for metric outputs, our analysis does not critically use all the properties of a metric. For instance, we do not require $d(z_1, z_2)$ to be strictly greater than zero for $z_1 \neq z_2$. An example of such a distance measure is the total variation distance that returns zero for two vectors that differ by a constant amount on each coordinate. Our proofs do implicitly use the symmetry property, but asymmetric distances can be converted to symmetric ones by taking the sum or the max of the distances in either directions. Perhaps the most important property of metrics that we use is the triangle inequality as it is critical for the robustness guarantee of the smoothed function. However, even this constraint may be partially relaxed. It is sufficient for the distance function $d$ to satisfy the triangle inequality approximately, i.e., $d(a, c) \leq \gamma(d(a, b) + d(b, c))$, for some constant $\gamma$. The theorems and lemmas can be adjusted to account for this approximation, e.g., the bound in theorem 1 will become $2\gamma R$. A commonly used distance measure for comparing images and documents is the cosine distance defined as the inner-product of two vectors after normalization. This distance can be shown to be proportional to the squared Euclidean distance between the normalized vectors which satisfies the relaxed version of triangle inequality for $\gamma = 2$.

These relaxations extend the scope of center smoothing to many commonly used distance measures that need not necessarily satisfy all the metric properties. For instance, perceptual distance metrics measure the distance between two images in some feature space rather than image space. Such distances align well with human judgements when the features are extracted from a deep neural network and are considered more natural measures for image similarity. For two images $I_1$ and $I_2$, let $\phi(I_1)$ and $\phi(I_2)$ be their feature representations. Then, for a distance function $d$ in the feature space that satisfies the relaxed triangle inequality, we can define a distance function $d_\phi(I_1, I_2) = d(\phi(I_1), \phi(I_2))$ in the image space, which also satisfies the relaxed triangle inequality.

5 High-dimensional Outputs

For functions with high-dimensional outputs, like high-resolution images, it might be difficult to compute the minimum enclosing ball (MEB) for a large number of points. The smoothing procedure needs us to store all the $n \sim 10^3 - 10^4$ sampled points until the MEB computation is complete, requiring $O(nk^3)$ space, where $k^3$ is the dimensionality of the output space. It does not allow us to sample the $n$ points in batches as is possible for the certification step. Also, computing the MEB by considering the pair-wise distances between all the sampled points is time-consuming and requires $O(n^2)$ pair-wise distance computations. To bring down the space and time requirements, we design another version (Smooth-HD, algorithm 3) of the smoothing procedure where we compute the MEB by first sampling a small number $n_0 \sim 30$ of candidate centers and then returning one of these candidate centers that has the smallest median distance to a separate sample of $n$ ($\gg n_0$) points.

We sample the $n$ points in batches and compute the distance $d(c_i, z_j)$ for each pair of candidate center $c_i$ and point $z_j$ in a batch. The rest of the procedure remains the same as algorithm 1. It only requires us to store batch-size number of output points and the $n_0$ candidate centers at any given time, significantly reducing the space complexity. Also, this procedure only requires $O(n_0 n)$ pair-wise distance computations. The key idea here is that, with very high probability ($> 1 - 10^{-3}$), at least one of the $n_0$ candidate centers will lie in the smallest ball that encloses at least $1/2 + \Delta_1$ probability mass of $f(x + P)$. Also, with high probability, at least half of the $n$ samples will lie in this ball too. Thus, the median distance of this candidate center to the $n$ samples is at most $2\gamma R(x, \Delta_1)$, after accounting for the factor of $\gamma$ in the relaxed version of the triangle inequality as discussed in section 4.
We apply center smoothing to certify a wide range of output metrics: Jaccard distance based on As is common in the randomized smoothing literature, we train our base models (except for the Algorithm 3 Smooth-HD

| Input: $x \in \mathbb{R}^k, \sigma, \Delta, \alpha_1$. |
| Output: $z \in M$. |
| Set $C = \{c_i\}_{i=1}^{n_0}$ s.t. $c_i \sim f(x + N(0, \sigma^2 I))$. |
| Set $\Delta_1 = \sqrt{\ln (2/\alpha_1)}/2n$. |
| Sample $Z = \{z_j\}_{j=1}^{n}$ s.t. $z_j \sim f(x + N(0, \sigma^2 I))$ in batches. |
| For each batch, compute pair-wise distances $d(c_i, z_j)$ for $c_i \in C$ and $z_j$ in the batch. |
| Compute the center $c \in C$ with the minimum median distance to the points in $Z$. |
| Re-sample $Z$ in batches. |
| Compute $p_{\Delta_1}$. |
| Set $\Delta_2 = 1/2 - p_{\Delta_1}$. |
| If $\Delta \leq \max(\Delta_1, \Delta_2)$, discard $c$ and abstain. |

Ignoring the probability that none of the $n_0$ points lie inside the ball, we can derive the following version of theorem[3]

Theorem 4. With probability at least $1 - \alpha_1$,

$$\forall x' \text{ s.t. } \|x - x'\|_2 \leq \epsilon_1, \ d(\hat{f}(x), \hat{f}(x')) \leq \gamma(1 + 2\gamma)\hat{R}$$

where $\alpha_1 = 2e^{-2n\Delta_1^2}$.

6 Experiments

We apply center smoothing to certify a wide range of output metrics: Jaccard distance based on intersection over union (IoU) of sets, total variation distances for images, and perceptual distance. We certify the bounding box generated by a face detector – a key component of most facial recognition systems – by guaranteeing the minimum overlap (measured using IoU) it must have with the output under an adversarial perturbation of the input. For instance, if $\epsilon_1 = 0.2$, the Jaccard distance (1-IoU) is guaranteed to be bounded by 0.2, which implies that the bounding box of a perturbed image must have at least 80% overlap with that of the clean image. We use a pre-trained face detection model for this experiment. We certify the perceptual distance of the output of a generative model (trained on ImageNet) that produces $128 \times 128$ RGB images using the above high-dimensional version of the smoothing procedure Smooth-HD. For total variation distance, we use simple, easy-to-train convolutional neural network based dimensionality reduction (autoencoder) and image reconstruction models. Our goal is to demonstrate the effectiveness of our method for a wide range of applications and so, we place less emphasis on the performance of the underlying models being smoothed. In each case, we show that our method is capable of generating certified guarantees without significantly degrading the performance of the underlying model. We provide additional experiments for other metrics and parameter settings in the appendix.

As is common in the randomized smoothing literature, we train our base models (except for the pre-trained ones) on noisy data with different noise levels $\sigma = 0.1, 0.2, \ldots, 0.5$ to make them more robust to input perturbations. We use $n = 10^4$ samples to estimate the smoothed function and $m = 10^6$ samples to generate certificates, unless stated otherwise. We set $\Delta = 0.05, \alpha_1 = 0.005$ and $\alpha_2 = 0.005$ as discussed in previous sections. We grow the smoothing noise $\sigma$ linearly with the input perturbation $\epsilon_1$. Specifically, we maintain $\epsilon_1 = h\sigma$ for different values of $h = 2, 1$ and 1.5 in our experiments. We plot the median certified output radius $\epsilon_2$ and the median smoothing loss, defined as the distance between the outputs of the base model and the smoothed model $d(f(x), \hat{f}(x))$, of fifty random test examples for different values of $\epsilon_1$. In all our experiments, we observe that both these quantities increase as the input radius $\epsilon_1$ increases, but the smoothing error remains significantly below the certified output radius. Also, increasing the value of $h$ improves the quality of the certificates (lower $\epsilon_2$). This could be due to the fact that for a higher $h$, the smoothing noise $\sigma$ is lower (keeping $\epsilon_1$ constant), which means that the radius of the minimum enclosing ball in the output space is smaller leading to a tighter certificate. We ran all our experiments on a single NVIDIA GeForce RTX 2080 Ti GPU in an internal cluster. Each of the fifty examples we certify took somewhere between 1-3 minutes depending on the underlying model.
6.1 Jaccard distance

It is known that facial recognition systems can be deceived to evade detection, impersonate authorized individuals and even render completely ineffective [50, 47, 14]. Most facial recognition systems first detect a region that contains a person’s face, e.g., a bounding box, and then use facial features to identify the individual in the image. To evade detection, an attacker may seek to degrade the quality of the bounding boxes produced by the detector and can even cause it to detect no box at all. Bounding boxes are often interpreted as sets and the their quality is measured as the amount of overlap with the desired output. When no box is output, we say the overlap is zero. The overlap between two sets is defined as the ratio of the size of the intersection between them to the size of their union (IoU). Thus, to certify the robustness of the output of a face detector, it makes sense to bound the worst-case IoU of the output of an adversarial input to that of a clean input. The corresponding distance function, known as Jaccard distance, is defined as

\[ d_J(A, B) = 1 - IoU(A, B) = 1 - \frac{|A \cap B|}{|A \cup B|}. \]

In this experiment, we certify the output of a pre-trained face detection model MTCNN [55] on the CelebA face dataset [37]. We set \( n = 5000 \) and \( m = 10000 \), and use default values for other parameters discussed above. Figure 3a plots the certified output radius \( \epsilon_2 \) and the smoothing error for \( h = 1 \) and 2. Part (b) compares the smoothed output (blue box) to the output of the base model (green box, mostly hidden behind the blue box) showing a significant overlap.

\[ IoU(A, B) = \frac{|A \cap B|}{|A \cup B|}, \quad d_J(A, B) = 1 - IoU(A, B) = 1 - \frac{|A \cap B|}{|A \cup B|}. \]

6.2 Perceptual Distance

Deep generative models like GANs and VAEs have been shown to be vulnerable to adversarial attacks [23]. One attack model is to produce an adversarial example that is close to the original input in the latent space, measured using \( \ell_2 \)-norm. The goal is to make the model generate a different looking image using a latent representation that is close to that of the original image. We apply center smoothing to a generative adversarial network BigGAN pre-trained on ImageNet images [3]. We use the version of the GAN that generates \( 128 \times 128 \) resolution ImageNet images from a set of 128 latent variables. Since we are interested in producing similar looking images for similar latent representations, a good output metric would be the perceptual distance between two images measured by LPIPS metric [56]. This distance function takes in two images, passes them through a deep neural network, such as VGG, and computes a weighted sum of the square of the differences of
Figure 4: Generative model for ImageNet: Part (a) plots the certified output radius $\varepsilon_2$ and the smoothing error for $h = 1$ and 1.5. Part (b) compares the output of the base model to that of the smoothed model.

The activations (after some normalization) produced by the two images. The process can be thought of as generating two feature vectors $\phi_1$ and $\phi_2$ for the two input images $I_1$ and $I_2$ respectively, then computing a weighted sum of the element-wise square of the differences between the two feature vectors, i.e.,

$$d(I_1, I_2) = \sum_i w_i (\phi_{1i} - \phi_{2i})^2$$

The square of differences metric can be shown to follow the relaxed triangle inequality for $\gamma = 2$. Therefore, the final bound on the certified output radius will be $\gamma (1 + 2\gamma) \hat{R} = 10 \hat{R}$. Figure 4a plots the median smoothing error and certified output radius $\varepsilon_2$ for fifty randomly picked latent vectors for $\varepsilon_1 = 0.01, 0.02, \ldots, 0.05$ and $h = 1, 1.5$. For these experiments, we set $n = 2000$, $m = 10^4$ and $\Delta = 0.8$. We use the modified smoothing procedure Smooth-HD (algorithm 3) for high-dimensional outputs presented in section 5 with a small batch size of 150 to accommodate the samples in memory. It takes about three minutes to smooth and certify each input on a single NVIDIA GeForce RTX 2080 Ti GPU in an internal cluster. Due to the higher factor of ten in the certified output radius in this case compared to our other experiments where the factor is three, the certified output radius increases faster with the input radius $\varepsilon_1$, but the smoothing error remains low showing that, in practice, the method does not significantly degrade the performance of the base model. Figure 4b shows that, visually, the smoothed output is not very different from the output of the base model. The input radii we certify for are lower in this case than our other experiments due to the low dimensionality (only 128 dimensions) of the input (latent) space as compared to the input (image) spaces in our other experiments.

### 6.3 Total Variation Distance

The total variation norm of a vector $x$ is defined as the sum of the magnitude of the difference between pairs of coordinates defined by a neighborhood set $N$. For a 1-dimensional array $x$ with $k$ elements, one can define the neighborhood as the set of consecutive elements.

$$TV(x) = \sum_{(i,j) \in N} |x_i - x_j|, \quad TV_1(x) = \sum_{i=1}^{k-1} |x_i - x_{i+1}|.$$  

Similarly, for a grayscale image represented by a $h \times w$ 2-dimensional array $x$, the neighborhood can be defined as the next element (pixel) in the row/column. In case of an RGB image, the difference between the neighboring pixels is a vector, whose magnitude can be computed using an $\ell_p$-norm. For, our experiments we use the $\ell_1$-norm.

$$TV_{RGB}(x) = \sum_{i=1}^{h-1} \sum_{j=1}^{w-1} \|x_{i,j} - x_{i+1,j}\|_1 + \|x_{i,j} - x_{i,j+1}\|_1.$$
The total variation distance between two images $I_1$ and $I_2$ can be defined as the total variation norm of the difference $I_1 - I_2$, i.e., $TVD(I_1, I_2) = TV(I_1 - I_2)$. The above distance defines a pseudometric over the space of images as it satisfies the symmetry property and the triangle inequality, but may violate the identity of indiscernibles as an image obtained by adding the same value to all the pixel intensities has a distance of zero from the original image. However, as noted in section 4, our certificates hold even for this setting.

We certify total variation distance for the problems of dimensionality reduction and image reconstruction on MNIST [11] and CIFAR-10 [24]. The base-model for dimensionality reduction is an autoencoder that uses convolutional layers in its encoder module to map an image down to a small number of latent variables. The decoder applies a set of de-convolutional operations to reconstruct the same image. We insert batch-norm layers in between these operations to improve performance. For image reconstruction, the goal is to recover an image from small number of measurements of the original image. We apply a transformation defined by Gaussian matrix $A$ on each image to obtain the measurements. The base model tries to reconstruct the original image from the measurements. The attacker, in this case, is assumed to add a perturbation in the measurement space instead of the image space (as in dimensionality reduction). The model first reverts the measurement vector to a vector in the image space by simply applying the pseudo-inverse of $A$ and then passes it through a similar autoencoder model as for dimensionality reduction. We present results for $\epsilon_1 = 0.2, 0.4, \ldots, 1.0$ and $h = 2, 1.5$ and use 256 latent dimensions and measurements for these experiments in figure 5. To put these plots in perspective, the maximum TVD between two CIFAR-10 images could be $6 \times 31 \times 31 = 5766$ and between MNIST images could be $2 \times 27 \times 27 = 1458$ (pixel values between 0 and 1).

7 Conclusion

Randomized smoothing can be extended beyond classification tasks to obtain provably robust models for problems where the quality of the output is measured using a distance metric. We design a procedure that can make any model of this kind provably robust against norm bounded adversarial perturbations of the input. In our experiments, we demonstrate that it can generate meaningful certificates under a wide variety of distance metrics without significantly compromising the quality of the base model. We also note that the metric requirements on the distance measure can be partially relaxed in exchange for weaker certificates.
In this work, we focus on $\ell_2$-norm bounded adversaries and the Gaussian smoothing distribution. An important direction for future investigation could be whether this method can be generalised beyond $\ell_p$-adversaries to more natural threat models, e.g., adversaries bounded by total variation distance, perceptual distance, cosine distance, etc. Center smoothing does not critically rely on the shape of the smoothing distribution or the threat model. Thus, improvements in these directions could potentially be coupled with our method to broaden the scope of provable robustness in machine learning.

A Proof of Theorem \[2\]

Let $z' = \hat{f}(x')$. Then, by definition of $\hat{f}$,

$$\mathbb{P} [f(X') \in B(z', \hat{r}(x', \Delta))] \geq \frac{1}{2} - \Delta,$$  

(6)

where $X' \sim x' + \mathcal{P}$ and

$$\hat{r}(x', \Delta) = \min_{z''} r \text{ s.t. } \mathbb{P}[f(X') \in B(z'', r)] \geq \frac{1}{2} + \Delta.$$  

And, by definition of $\hat{R}$,

$$\mathbb{P}[f(X') \in B(\hat{f}(x), \hat{R})] \geq \frac{1}{2} + \Delta.$$  

(7)

Therefore, from (6) and (7), $B(z', \hat{r}(x', \Delta))$ and $B(\hat{f}(x), \hat{R})$ must have a non-empty intersection. Let, $y$ be a point in that intersection. Then,

$$d(\hat{f}(x), \hat{f}(x')) \leq d(\hat{f}(x), y) + d(y, z')$$

$$\leq \hat{r}(x', \Delta) + \hat{R}.$$  

Since, by definition, $\hat{r}(x', \Delta)$ is the radius of the smallest ball with $1/2 + \Delta$ probability mass of $f(x' + \mathcal{P})$ over all possible centers in $\mathbb{R}^k$ and $\hat{R}$ is the radius of the smallest such ball centered at $\hat{f}(x)$, we must have $\hat{r}(x', \Delta) \leq \hat{R}$. Therefore,

$$d(\hat{f}(x), \hat{f}(x')) \leq 2\hat{R}.$$

B Proof of Lemma \[1\]

Consider the smallest ball $B(z', \hat{r}(x, \Delta_1))$ that encloses at least $1/2 + \Delta_1$ probability mass of $f(x + \mathcal{P})$. By Hoeffding’s inequality, with at least $1 - e^{-2n\Delta_1^2}$ probability, at least half the points in $Z$ must be in this ball. Since, $r$ is the radius of the minimum enclosing ball that contains at least half of the points in $Z$, we have $r \leq \hat{r}(x, \Delta_1)$.

C Proof of Theorem \[3\]

$\beta$-MEB($Z, 1/2$) computes a $\beta$-approximation of the minimum enclosing ball that contains at least half of the points of $Z$. Therefore, by lemma \[1\] with probability at least $1 - e^{-2n\Delta_1^2}$,

$$\beta$-MEB($Z, 1/2$) \leq \beta \hat{r}(x, \Delta_1) \leq \beta \hat{r}(x, \Delta),$$

since $\Delta \geq \Delta_1$. Thus, the procedure to compute $\hat{f}$, if succeeds, will output a point $z \in \mathbb{R}^k$ which, with probability at least $1 - 2e^{-2n\Delta_1^2}$, will satisfy,

$$\mathbb{P} [f(X) \in B(z, \beta \hat{r}(x, \Delta))] \geq \frac{1}{2} - \Delta.$$  

Now, using the definition of $\hat{R}$ and following the same reasoning as theorem \[2\], we can say that,

$$d(\hat{f}(x), \hat{f}(x')) \leq \beta \hat{r}(x', \Delta) + \hat{R}$$

$$\leq (1 + \beta)\hat{R}.$$  

D Proof of Lemma \[2\]

Given $z = \hat{f}(x)$, define a random variable $Q = d(z, f(X))$, where is $X \sim x + \mathcal{P}$. For $m$ i.i.d. samples of $X$, the values of $Q$ are independently and identically distributed. Let $F(r)$ denote the true
cumulative distribution function of $Q$ and define the empirical cdf $F_m(r)$ to be the fraction of the $m$ samples of $Q$ that are less than or equal to $r$, i.e.,

$$F_m(r) = \frac{1}{m} \sum_{i=1}^{m} 1_{\{Q_i \leq r\}}$$

Using the Dvoretzky–Kiefer–Wolfowitz inequality, we have,

$$\mathbb{P}\left[ \sup_{r \in \mathbb{R}} (F_m(r) - F(r)) > \epsilon \right] \leq e^{-2m\epsilon^2}$$

for $\epsilon \geq \sqrt{\frac{1}{2m} \ln 2}$. Setting $e^{-2m\epsilon^2} = \alpha_2$ for some $\alpha_2 \leq 1/2$, we have,

$$\sup_{r \in \mathbb{R}} (F_m(r) - F(r)) < \sqrt{\frac{\ln (1/\alpha_2)}{2m}}$$

with probability at least $1 - \alpha_2$. Set $r = \tilde{R}_q$, the $q$th quantile of of the $m$ samples. Then,

$$F(\tilde{R}_q) > F_m(\tilde{R}_q) - \sqrt{\frac{\ln (1/\alpha_2)}{2m}}$$

or, $\mathbb{P}\left[ Q \leq \tilde{R}_q \right] > q - \sqrt{\frac{\ln (1/\alpha_2)}{2m}} = p$.

With probability $1 - \alpha_2$,

$$\mathbb{P}\left[ f(X) \in B(\bar{f}(x), \tilde{R}_q) \right] > p.$$

### E Angular Distance

A common measure for similarity of two vectors $A$ and $B$ is the cosine similarity between them, defined as below:

$$\cos(A, B) = \frac{A \cdot B}{\|A\|_2 \|B\|_2} = \frac{\sum_i A_i B_i}{\sqrt{\sum_j A_j^2} \sqrt{\sum_k B_k^2}}.$$

In order to convert it into a distance, we can compute the angle between the two vectors by taking the cosine inverse of the above similarity measure, which is known as angular distance:

$$AD(A, B) = \cos^{-1}(\cos(A, B))/\pi.$$

Angular distance always remains between 0 and 1, and similar to the total variation distance, angular distance also defines a pseudometric on the output space. We repeat the same experiments with the same models and hyper-parameter settings as for total variation distance (figure 6). The results are similar in trend in all the experiments conducted, showing that center smoothing can be reliably applied to a vast range of output metrics to obtain similar robustness guarantees.
