Abstract

The traditional mention-pair model for coreference resolution cannot capture information beyond mention pairs for both learning and testing. To deal with this problem, we present an expressive entity-mention model that performs coreference resolution at an entity level. The model adopts the Inductive Logic Programming (ILP) algorithm, which provides a relational way to organize different knowledge of entities and mentions. The solution can explicitly express relations between an entity and the contained mentions, and automatically learn first-order rules important for coreference decision. The evaluation on the ACE data set shows that the ILP based entity-mention model is effective for the coreference resolution task.

1 Introduction

Coreference resolution is the process of linking multiple mentions that refer to the same entity. Most of previous work adopts the mention-pair model, which recasts coreference resolution to a binary classification problem of determining whether or not two mentions in a document are co-referring (e.g. Aone and Bennett (1995); McCarthy and Lehnert (1995); Soon et al. (2001); Ng and Cardie (2002)). Although having achieved reasonable success, the mention-pair model has a limitation that information beyond mention pairs is ignored for training and testing. As an individual mention usually lacks adequate descriptive information of the referred entity, it is often difficult to judge whether or not two mentions are talking about the same entity simply from the pair alone.

An alternative learning model that can overcome this problem performs coreference resolution based on entity-mention pairs (Luo et al., 2004; Yang et al., 2004b). Compared with the traditional mention-pair counterpart, the entity-mention model aims to make coreference decision at an entity level. Classification is done to determine whether a mention is a referent of a partially found entity. A mention to be resolved (called active mention henceforth) is linked to an appropriate entity chain (if any), based on classification results.

One problem that arises with the entity-mention model is how to represent the knowledge related to an entity. In a document, an entity may have more than one mention. It is impractical to enumerate all the mentions in an entity and record their information in a single feature vector, as it would make the feature space too large. Even worse, the number of mentions in an entity is not fixed, which would result in variant-length feature vectors and make trouble for normal machine learning algorithms. A solution seen in previous work (Luo et al., 2004; Culotta et al., 2007) is to design a set of first-order features summarizing the information of the mentions in an entity, for example, “whether the entity has any mention that is a name alias of the active mention?” or “whether most of the mentions in the entity have the same head word as the active mention?” These features, nevertheless, are designed in an ad-hoc manner and lack the capability of describing each individual mention in an entity.

In this paper, we present a more expressive entity-
 Eve of every possible pair of mentions from the two entities are obtained based on the information of the entity, to make coreference decision. Hence, our model has a more powerful representation capability than the traditional mention-pair or entity-mention model. And our experimental results on the ACE data set shows the model is effective for coreference resolution.

2 Related Work

There are plenty of learning-based coreference resolution systems that employ the mention-pair model. A typical one of them is presented by Soon et al. (2001). In the system, a training or testing instance is formed for two mentions in question, with a feature vector describing their properties and relationships. At a testing time, an active mention is checked against all its preceding mentions, and is linked with the closest one that is classified as positive. The work is further enhanced by Ng and Cardie (2002) by expanding the feature set and adopting a “best-first” linking strategy.

Recent years have seen some work on the entity-mention model. Luo et al. (2004) propose a system that performs coreference resolution by doing search in a large space of entities. They train a classifier that can determine the likelihood that an active mention should belong to an entity. The entity-level features are calculated with an “Any-X” strategy: an entity-mention pair would be assigned a feature X, if any mention in the entity has the feature X.

Yang et al. (2004b) suggest an entity-based coreference resolution system. The model adopted in the system is similar to the mention-pair model, except that the entity information (e.g., the global number/gender agreement) is considered as additional features of a mention in the entity.

McCallum and Wellner (2003) propose several graphical models for coreference analysis. These models aim to overcome the limitation that pairwise coreference decisions are made independently of each other. The simplest model conditions coreference on mention pairs, but enforces dependency by calculating the distance of a node to a partition (i.e., the probability that an active mention belongs to an entity) based on the sum of its distances to all the nodes in the partition (i.e., the sum of the probability of the active mention co-referring with the mentions in the entity).

Inductive Logic Programming (ILP) has been applied to some natural language processing tasks, including parsing (Mooney, 1997), POS disambiguation (Cussens, 1996), lexicon construction (Claveau et al., 2003), WSD (Specia et al., 2007), and so on. However, to our knowledge, our work is the first effort to adopt this technique for the coreference resolution task.

3 Modelling Coreference Resolution

Suppose we have a document containing n mentions \( \{m_j : 1 < j < n\} \), in which \( m_j \) is the jth mention occurring in the document. Let \( e_i \) be the ith entity in the document. We define

\[
P(L | e_i, m_j),
\]

the probability that a mention belongs to an entity. Here the random variable \( L \) takes a binary value and is 1 if \( m_j \) is a mention of \( e_i \).

By assuming that mentions occurring after \( m_j \) have no influence on the decision of linking \( m_j \) to an entity, we can approximate (1) as:

\[
P(L | e_i, m_j) \propto P(L | \{m_k \in e_i, 1 \leq k \leq j - 1\}, m_j) \quad (2)
\]

\[
P(L | m_k, m_j) \quad (3)
\]

(3) further assumes that an entity-mention score can be computed by using the maximum mention-
pair score. Both (2) and (1) can be approximated
with a machine learning method, leading to the tra-
ditional mention-pair model and the entity-mention
model for coreference resolution, respectively.

The two models will be described in the next sub-
sections, with the sample text in Table 1 used for
demonstration. In the table, a mention \( m \) is high-
lighted as \([ m ]_{\text{mid}}^{\text{eid}}\), where \( \text{mid} \) and \( \text{eid} \) are the IDs
for the mention and the entity to which it belongs,
respectively. Three entity chains can be found in the
text, that is,
\[
e_1 : \text{Microsoft Corp.} \cdot \text{- its} \cdot \text{- The company}
\]
\[
e_2 : \text{its new CEO} \cdot \text{- he}
\]
\[
e_3 : \text{yesterday}
\]

### 3.1 Mention-Pair Model

As a baseline, we first describe a learning framework
with the mention-pair model as adopted in the work
by Soon et al. (2001) and Ng and Cardie (2002).

In the learning framework, a training or testing
instance has the form of \( i\{m_k, m_j\} \), in which \( m_j \) is
an active mention and \( m_k \) is a preceding mention.
An instance is associated with a vector of features,
which is used to describe the properties of the two
mentions as well as their relationships. Table 2 sum-
marizes the features used in our study.

For training, given each encountered anaphoric
mention \( m_j \) in a document, one single positive training
instance is created for \( m_j \) and its closest an-
tecedent. And a group of negative training in-
stances is created for every intervening mentions
between \( m_j \) and the antecedent. Consider the ex-
ample text in Table 1, for the pronoun “he”, three instances are generated: \( i(\text{“he”}) \), \( i(\text{“yesterday”}; \text{“he”}) \),
and \( i(\text{“its new CEO”}; \text{“he”}) \). Among them, the first two are labelled as negative
while the last one is labelled as positive.

Based on the training instances, a binary classifier
can be generated using any discriminative learning
algorithm. During resolution, an input document is
processed from the first mention to the last. For each
encountered mention \( m_j \), a test instance is formed
for each preceding mention, \( m_k \). This instance is
presented to the classifier to determine the coref-
ence relationship. \( m_j \) is linked with the mention that
is classified as positive (if any) with the highest con-
fidence value.

### 3.2 Entity-Mention Model

The mention-based solution has a limitation that in-
formation beyond a mention pair cannot be captured.
As an individual mention usually lacks complete de-
scription about the referred entity, the coreference
relationship between two mentions may be not clear,
which would affect classifier learning. Consider
a document with three coreferential mentions “Mr.
Powell”, “he”, and “Powell”, appearing in that or-
der. The positive training instance \( i(\text{“he”}, \text{“Powell”}) \)
is not informative, as the pronoun “he” itself disclo-
ses nothing but the gender. However, if the whole
entity is considered instead of only one mention, we
can know that “he” refers to a male person named
“Powell”. And consequently, the coreference rela-
tionships between the mentions would become more
obvious.

The mention-pair model would also cause errors
at a testing time. Suppose we have three mentions
“Mr. Powell”, “Powell”, and “she” in a document.
The model tends to link “she” with “Powell” be-
cause of their proximity. This error can be avoided,
if we know “Powell” belongs to the entity starting
with “Mr. Powell”, and therefore refers to a male
person and cannot co-refer with “she”.

The entity-mention model based on Eq. (2) per-
forms coreference resolution at an entity-level. For
simplicity, the framework considered for the entity-
mention model adopts similar training and testing
procedures as for the mention-pair model. Specifi-
cally, a training or testing instance has the form of
\( i\{e_i, m_j\} \), in which \( m_j \) is an active mention and \( e_i \)
is a partial entity found before \( m_j \). During train-
ing, given each anaphoric mention \( m_j \), one single
positive training instance is created for the entity to
which \( m_j \) belongs. And a group of negative train-
ing instances is created for every partial entity whose
last mention occurs between \( m_j \) and the closest an-
tecedent of \( m_j \).

See the sample in Table 1 again. For the pronoun
“he”, the following three instances are generated for

| Microsoft Corp. | its | new CEO |
|-----------------|-----|---------|
| yesterday       |     |         |
entity $e_1$, $e_3$ and $e_2$:  
\[i(\{\text{"Microsoft Corp."}, \text{"its"}, \text{"The company"}\}, \text{"he"}), \]
\[i(\{\text{"yesterday"}, \text{"he"}\}), \]
\[i(\{\text{"its new CEO"}, \text{"he"}\}). \]

Among them, the first two are labelled as negative, while the last one is positive.

The resolution is done using a greedy clustering strategy. Given a test document, the mentions are processed one by one. For each encountered mention $m_j$, a test instance is formed for each partial entity found so far, $e_j$. This instance is presented to the classifier. $m_j$ is appended to the entity that is classified as positive (if any) with the highest confidence value. If no positive entity exists, the active mention is deemed as non-anaphoric and forms a new entity. The process continues until the last mention of the document is reached.

One potential problem with the entity-mention model is how to represent the entity-level knowledge. As an entity may contain more than one candidate and the number is not fixed, it is impractical to enumerate all the mentions in an entity and put their properties into a single feature vector. As a baseline, we follow the solution proposed in (Luo et al., 2004) to design a set of first-order features. The features are similar to those for the mention-pair model as shown in Table 2, but their values are calculated at an entity level. Specifically, the lexical and grammatical features are computed by testing any mention $e_i$ in the entity against the active mention, for example, the feature nameAlias is assigned value 1 if at least one mention in the entity is a name alias of the active mention. The distance feature (i.e., sentDist) is the minimum distance between the mentions in the entity and the active mention.

The above entity-level features are designed in an ad-hoc way. They cannot capture the detailed information of each individual mention in an entity. In the next section, we will present a more expressive entity-mention model by using ILP.

4 Entity-mention Model with ILP

4.1 Motivation

The entity-mention model based on Eq. (2) requires relational knowledge that involves information of an active mention ($m_j$), an entity ($e_i$), and the mentions in the entity ($\{m_k \in e_i\}$). However, normal machine learning algorithms work on attribute-value vectors, which only allows the representation of atomic proposition. To learn from relational knowledge, we need an algorithm that can express first-order logic. This requirement motivates our use of Inductive Logic Programming (ILP), a learning algorithm capable of inferring logic programs. The relational nature of ILP makes it possible to explicitly represent relations between an entity and its mentions, and thus provides a powerful expressiveness for the coreference resolution task.

...
ILP uses logic programming as a uniform representation for examples, background knowledge and hypotheses. Given a set of positive and negative example $E = E^+ \cup E^-$, and a set of background knowledge $K$ of the domain, ILP tries to induce a set of hypotheses $h$ that covers most of $E^+$ with no $E^-$, i.e., $K \land h \models E^+$ and $K \land h \not\models E^-$. In our study, we choose ALEPH\textsuperscript{2}, an ILP implementation by Srinivasan (2000) that has been proven well suited to deal with a large amount of data in multiple domains. For its routine use, ALEPH follows a simple procedure to induce rules. It first selects an example and builds the most specific clause that entertains the example. Next, it tries to search for a clause more general than the bottom one. The best clause is added to the current theory and all the examples made redundant are removed. The procedure repeats until all examples are processed.

4.2 Apply ILP to coreference resolution

Given a document, we encode a mention or a partial entity with a unique constant. Specifically, $m_j$ represents the $j$th mention (e.g., $m_6$ for the pronoun “he”). $e_{i,j}$ represents the partial entity $i$ before the $j$th mention. For example, $e_{1,6}$ denotes the part of $e_1$ before $m_6$, i.e., \{“Microsoft Corp.”, “its”, “the company”\}, while $e_{1,5}$ denotes the part of $e_1$ before $m_5$ (“The company”), i.e., \{“Microsoft Corp.”, “its”\}.

Training instances are created as described in Section 3.2 for the entity-mention model. Each instance is recorded with a predicate link($e_{i,j}$, $m_j$), where $m_j$ is an active mention and $e_{i,j}$ is a partial entity. For example, the three training instances formed by the pronoun “he” are represented as follows:

\begin{align*}
\text{link}(e_{1,6}, m_6). \\
\text{link}(e_{3,6}, m_6). \\
\text{link}(e_{2,6}, m_6).
\end{align*}

The first two predicates are put into $E^-$, while the last one is put to $E^+$. The background knowledge for an instance link($e_{i,j}$, $m_j$) is also represented with predicates, which are divided into the following types:

1. Predicates describing the information related to $e_{i,j}$ and $m_j$. The properties of $m_j$ are presented with predicates like $f(m, v)$, where $f$ corresponds to a feature in the first part of Table 2 (removing the suffix \_num), and $v$ is its value. For example, the pronoun “he” can be described by the following predicates:

\begin{align*}
defNP(m_6, 0). \quad \text{indefNP}(m_6, 0). \\
ameNP(m_6, 0). \quad \text{pron}(m_6, 1). \\
bareNP(m_6, 0).
\end{align*}

The predicates for the relationships between $e_{i,j}$ and $m_j$ take a form of $f(e, m, v)$. In our study, we consider the number agreement (entNumAgree) and the gender agreement (entGenderAgree) between $e_{i,j}$ and $m_j$. $v$ is 1 if all of the mentions in $e_{i,j}$ have consistent number/gender agreement with $m_j$, e.g., entNumAgree($e_{1,6}, m_6, 1$).

2. Predicates describing the belonging relations between $e_{i,j}$ and its mentions. A predicate has\_mention(e, $m$) is used for each mention in $e$ \textsuperscript{3}. For example, the partial entity $e_{1,6}$ has three mentions, $m_1$, $m_2$ and $m_5$, which can be described as follows:

\begin{align*}
\text{has\_mention}(e_{1,6}, m_1). \\
\text{has\_mention}(e_{1,6}, m_2). \\
\text{has\_mention}(e_{1,6}, m_5).
\end{align*}

3. Predicates describing the information related to $m_j$ and each mention $m_k$ in $e_{i,j}$. The predicates for the properties of $m_k$ correspond to the features in the second part of Table 2 (removing the suffix \_mk), while the predicates for the relationships between $m_j$ and $m_k$ correspond to the features in the third part of Table 2. For example, given the two mentions $m_1$ (“Microsoft Corp.”) and $m_6$ (“he”), the following predicates can be applied:

\begin{align*}
\text{nameNP}(m_1, 0). \\
\text{pron}(m_1, 0). \\
\text{sentDist}(m_1, m_6, 0). \\
\text{...} \\
\text{nameAlias}(m_1, m_6, 0). \\
\text{sentDist}(m_1, m_6, 1). \\
\text{...}
\end{align*}

\text{the last two predicates represent that $m_1$ and $m_6$ are considered to be the same.}

\textsuperscript{3}If an active mention $m_j$ is a pronoun, only the previous mentions in two sentences apart are recorded by has\_mention, while the farther ones are ignored as they have less impact on the resolution of the pronoun.
$m_6$ are not name alias, and are one sentence apart.

By using the three types of predicates, the different knowledge related to entities and mentions are integrated. The predicate $\text{has\_mention}$ acts as a bridge connecting the entity-mention knowledge and the mention-pair knowledge. As a result, when evaluating the coreference relationship between an active mention and an entity, we can make use of the “global” information about the entity, as well as the “local” information of each individual mention in the entity.

From the training instances and the associated background knowledge, a set of hypotheses can be automatically learned by ILP. Each hypothesis is output as a rule that may look like:

$$\text{link}(A, B) :- \text{has\_mention}(A, C), \ldots, \text{prediN}. \forall A, B (\text{predi1} \land \text{predi2} \land \ldots \land \text{prediN}) \land \exists C (\text{has\_mention}(A, C) \land \ldots \land \text{prediN}) \rightarrow \text{link}(A, B)$$

Consider an example rule generated from our system:

$$\text{link}(A, B) :- \text{has\_mention}(A, C), \text{numAgree}(B, C, 1), \text{strMatch\_Head}(B, C, 1), \text{bareNP}(C, 1).$$

Here, variables $A$ and $B$ stand for an entity and an active mention in question. The first-order logic is implemented by using non-instantiated arguments $C$ in the predicate $\text{has\_mention}$. This rule states that a mention $B$ should belong to an entity $A$, if there exists a mention $C$ in $A$ such that $C$ is a bare noun phrase with the same head string as $B$, and matches in number with $B$. In this way, the detailed information of each individual mention in an entity can be captured for resolution.

A rule is applicable to an instance $\text{link}(e, m)$, if the background knowledge for the instance can be described by the predicates in the body of the rule. Each rule is associated with a score, which is the accuracy that the rule can produce for the training instances.

The learned rules are applied to resolution in a similar way as described in Section 3.2. Given an active mention $m$ and a partial entity $e$, a test instance $\text{link}(e, m)$ is formed and tested against every rule in the rule set. The confidence that $m$ should belong to $e$ is the maximal score of the applicable rules. An active mention is linked to the partial entity with the highest confidence value (above 0.5), if any.

## 5 Experiments and Results

### 5.1 Experimental Setup

In our study, we did evaluation on the ACE-2 V1.0 corpus (NIST, 2003), which contains two data sets, training and devtest, used for training and testing respectively. Each of these sets is further divided into three domains: newswire (NWire), newspaper (NPaper), and broadcast news (BNews). The number of entities with more than one mention, as well as the number of the contained mentions, is summarized in Table 3.

| Domain | #entity | #mention | #entity | #mention |
|--------|---------|----------|---------|----------|
| NWire  | 1678    | 9861     | 411     | 2304     |
| NPaper | 1528    | 10277    | 365     | 2290     |
| BNews  | 1695    | 8986     | 468     | 2493     |

Table 3: statistics of entities (length $>1$) and contained mentions

For both training and resolution, an input raw document was processed by a pipeline of NLP modules including Tokenizer, Part-of-Speech tagger, NP Chunker and Named-Entity (NE) Recognizer. Trained and tested on Penn WSJ TreeBank, the POS tagger could obtain an accuracy of 97% and the NP chunker could produce an F-measure above 94% (Zhou and Su, 2000). Evaluated for the MUC-6 and MUC-7 Named-Entity task, the NER module (Zhou and Su, 2002) could provide an F-measure of 96.6% (MUC-6) and 94.1% (MUC-7). For evaluation, Vilain et al. (1995)’s scoring algorithm was adopted to compute the recall and precision of resolution.

By default, the ALEPH algorithm only generates rules that have 100% accuracy for the training data. And each rule contains at most three predicates. To accommodate for coreference resolution, we loosened the restrictions to allow rules that have above 50% accuracy and contain up to ten predicates. Default parameters were applied for all the other settings in ALEPH as well as other learning algorithms.
5.2 Results and Discussions

Table 4 lists the performance of different coreference resolution systems. For comparison, we first examined the C4.5 algorithm\(^4\) which is widely used for the coreference resolution task. The first line of the table shows the baseline system that employs the traditional mention-pair model (MP) as described in Section 3.1. From the table, our baseline system achieves a recall of around 66%-68% and a precision of around 50%-60%. The overall F-measure for NWire, NPaper and BNews is 60.4%, 57.9% and 62.9% respectively. The results are comparable to those reported in (Ng, 2005) which uses similar features and gets an F-measure ranging in 50-60% for the same data set. As our system relies only on simple and knowledge-poor features, the achieved F-measure is around 2-4% lower than the state-of-the-art systems do, like (Ng, 2007) and (Yang and Su, 2007) which utilized sophisticated semantic or real-world knowledge. Since ILP has a strong capability in knowledge management, our system could be further improved if such helpful knowledge is incorporated, which will be explored in our future work.

The second line of Table 4 is for the system that employs the entity-mention model (EM) with “Any-X” based entity features, as described in Section 3.2. We can find that the EM model does not show superiority over the baseline MP model. It achieves a higher precision (up to 2.6%), but a lower recall (2.9%), than MP. As a result, we only see ±0.4% difference between the F-measure. The results are consistent with the reports by Luo et al. (2004) that the entity-mention model with the “Any-X” first-order features performs worse than the normal mention-pair model. In our study, we also tested the “Most-X” strategy for the first-order features as in (Culotta et al., 2007), but got similar results without much difference (±0.5% F-measure) in performance. Besides, as with our entity-mention predicates described in Section 4.2, we also tried the “All-X” strategy for the entity-level agreement features, that is, whether all mentions in a partial entity agree in number and gender with an active mention. However, we found this bring no improvement against the “Any-X” strategy.

As described, given an active mention \(m_j\), the MP model only considers the mentions between \(m_j\) and its closest antecedent. By contrast, the EM model considers not only these mentions, but also their antecedents in the same entity link. We were interested in examining what if the MP model utilizes all the mentions in an entity as the EM model does. As shown in the third line of Table 4, such a solution damages the performance; while the recall is at the same level, the precision drops significantly (up to 12%) and as a result, the F-measure is even lower than the original MP model. This should be because a mention does not necessarily have direct coreference relationships with all of its antecedents. As the MP model treats each mention-pair as an independent instance, including all the antecedents would produce many less-confident positive instances, and thus adversely affect training.

The second block of the table summarizes the performance of the systems with ILP. We were first concerned with how well ILP works for the mention-pair model, compared with the normally used algorithm C4.5. From the results shown in the fourth line of Table 4, ILP exhibits the same capability in

\[\text{Table 4: Results of different systems for coreference resolution}\]

|                | NWire |     |     | NPaper |     |     | BNews |     |     |
|----------------|-------|-----|-----|--------|-----|-----|-------|-----|-----|
|                | R     | P   | F   | R      | P   | F   | R      | P   | F   |
| C4.5           |       |     |     |        |     |     |        |     |     |
| - Mention-Pair | 68.2  | 54.3| 60.4| 67.3   | 50.8| 57.9| 66.5   | 59.5| 62.9|
| - Entity-Mention| 66.8 | 55.0| 60.3| 64.2   | 53.4| 58.3| 64.6   | 60.6| 62.5|
| - Mention-Pair (all mentions in entity) | 66.7 | 49.3| 56.7| 65.8   | 48.9| 56.1| 66.5   | 47.6| 55.4|
| ILP            |       |     |     |        |     |     |        |     |     |
| - Mention-Pair | 66.1  | 54.8| 59.5| 65.6   | 54.8| 59.7| 63.5   | 60.8| 62.1|
| - Entity-Mention| 65.0 | 58.9| 61.8| 63.4   | 57.1| 60.1| 61.7   | 65.4| 63.5|

\(^4\)http://www.rulequest.com/see5-info.html

used in the experiments.

As described, given an active mention \(m_j\), the MP model only considers the mentions between \(m_j\) and its closest antecedent. By contrast, the EM model considers not only these mentions, but also their antecedents in the same entity link. We were interested in examining what if the MP model utilizes all the mentions in an entity as the EM model does. As shown in the third line of Table 4, such a solution damages the performance; while the recall is at the same level, the precision drops significantly (up to 12%) and as a result, the F-measure is even lower than the original MP model. This should be because a mention does not necessarily have direct coreference relationships with all of its antecedents. As the MP model treats each mention-pair as an independent instance, including all the antecedents would produce many less-confident positive instances, and thus adversely affect training.

The second block of the table summarizes the performance of the systems with ILP. We were first concerned with how well ILP works for the mention-pair model, compared with the normally used algorithm C4.5. From the results shown in the fourth line of Table 4, ILP exhibits the same capability in
the resolution; it tends to produce a slightly higher precision but a lower recall than C4.5 does. Overall, it performs better in F-measure (1.8%) for Npaper, while slightly worse (<1%) for Nwire and BNews. These results demonstrate that ILP could be used as a good classifier learner for the mention-pair model.

The fifth line of Table 4 is for the ILP based entity-mention model (described in Section 4.2). We can observe that the model leads to a better performance than all the other models. Compared with the system with the MP model (under ILP), the EM version is able to achieve a higher precision (up to 4.6% for BNews). Although the recall drops slightly (up to 1.8% for BNews), the gain in the precision could compensate it well; it beats the MP model in the overall F-measure for all three domains (2.3% for Nwire, 0.4% for Npaper, 1.4% for BNews). Especially, the improvement in NWire and BNews is statistically significant under a 2-tailed t test (p < 0.05). Compared with the EM model with the manually designed first-order feature (the second line), the ILP-based EM solution also yields better performance in precision (with a slightly lower recall) as well as the overall F-measure (1.0% - 1.8%).

The improvement in precision against the mention-pair model confirms that the global information beyond a single mention pair, when being considered for training, can make coreference relations clearer and help classifier learning. The better performance against the EM model with heuristically designed features also suggests that ILP is able to learn effective first-order rules for the coreference resolution task.

In Figure 1, we illustrate part of the rules produced by ILP for the entity-mention model (NWire domain), which shows how the relational knowledge of entities and mentions is represented for decision making. An interesting finding, as shown in the last rule of the table, is that multiple non-instantiated arguments (i.e. \( C \) and \( D \)) could possibly appear in the same rule. According to this rule, a pronominal mention should be linked with a partial entity which contains a named-entity and contains an indefinite NP in a subject position. This supports the claims in (Yang et al., 2004a) that coreferential information is an important factor to evaluate a candidate antecedent in pronoun resolution. Such complex logic makes it possible to capture information of multiple mentions in an entity at the same time, which is difficult to implemented in the mention-pair model and the ordinary entity-mention model with heuristic first-order features.

6 Conclusions

This paper presented an expressive entity-mention model for coreference resolution by using Inductive Logic Programming. In contrast to the traditional mention-pair model, our model can capture information beyond single mention pairs for both training and testing. The relational nature of ILP enables our model to explicitly express the relations between an entity and its mentions, and to automatically learn the first-order rules effective for the coreference resolution task. The evaluation on ACE data set shows that the ILP based entity-model performs better than the mention-pair model (with up to 2.3% increase in F-measure), and also beats the entity-mention model with heuristically designed first-order features.

Our current work focuses on the learning model that calculates the probability of a mention belonging to an entity. For simplicity, we just use a greedy clustering strategy for resolution, that is, a mention is linked to the current best partial entity. In our future work, we would like to investigate more sophisticated clustering methods that would lead to global optimization, e.g., by keeping a large search space (Luo et al., 2004) or using integer programming (Denis and Baldrige, 2007). We hope that such efforts could further improve the coreference resolution performance.
