Learning from Demonstrations, Active learning

1 INTRODUCTION AND RELATED WORK
Imagine a future where a domestic robot ships with a state-of-the-art learning from demonstrations (LfD) system to learn household tasks. You would like the robot to set the dinner table for you when you get home at dinner time. After you demonstrate how to set the dinner table a couple of times. Would you be confident that robot will not try to place the saucer on top of the cup, or finish as much of the task as possible if an object was missing?

Formal languages like linear temporal logic (LTL) are ideal for specifying temporal properties pertaining to the dinner setting task due to their unambiguous semantics and expressivity. However, formal languages are an unwieldy tool for an untrained user. This has lead to an interest in developing models to infer formal specifications from data provided through intuitive modalities. For example, there exist models to infer LTL formulas from demonstrations [17],[12], natural language instructions [16],[9], and preferences elicited from multiple experts [11]. However these modalities are inherently ambiguous and potentially mutually contradictory. Often, there is no ‘correct’ answer, and the task specification is best described as a belief over multiple LTL formulas \( P(\phi) \). Our proposed approach is to decompose the problem of training a robot into inferring the specification [17] as a belief over candidate LTL formulas, followed by computing policies that best satisfy this belief [18]. Further, I propose an interactive training framework (Figure 1c) that allows the user to begin the robot training by providing demonstrations, and later provide feedback on the acceptability of task executions performed by the robot.

Argall et al. [1] and Chernova et al. [7] provide a comprehensive survey of methods for robot learning from demonstrations (LfD). Prior research into specification inference from demonstrations [10, 13, 21, 22] generate a point estimate of the specifications; this makes them unsuitable in scenario when multiple hypotheses are equally valid. Our prior work on Bayesian specification inference [17] computes the belief over candidate LTL formulas thus providing an estimate of the model’s (un)certainty.

Specification inference from a batch of demonstrations yields an initial belief over specifications, however active learning can guide further exploration to reduce the uncertainty of the distribution. Cakmak et al. [4, 5] developed a taxonomy of types of queries that can be asked to obtain a better understanding of task specifications. Biyik et al. [2, 3] have designed inference models that learn the reward function for a task based on queries that elicit the user’s preference over multiple trajectories. However, the prior work has largely focused on tasks with a Markovian reward function. Temporal tasks that we consider do not satisfy the Markov assumption as they require the entire state history to evaluate acceptability. Our proposed research extends active learning to tasks that can be described by formulas belonging to a well-defined segment of LTL.

Adopting LTL specifications as goal specifications would require abandoning the Markov assumption. Algorithms for planning with...
As a part of our prior research [17], we developed a probabilistic approach to compute an optimal policy for the learner. As depicted in Figure 1b, a robot trained using the PUnS formulation for the table setting task was able to reliably set the dinner table with a very small error rate (~ 10\(^{-4}\) as estimated through simulations).

4 PROPOSED RESEARCH

Bayesian specification inference and PUnS can be used in conjunction with each other to allow a robot to learn a task given a batch of demonstration data. However, the initial belief \(P(\phi)\) and the minimal FSM constructed for PUnS allow the learner to identify a task execution whose acceptability is the most uncertain. This execution can then be demonstrated back to the user to ascertain whether it is acceptable or unacceptable (\(Q\) represents the query and the user's assessment). Given \(Q\), the learner can once again apply Bayesian specification inference; this time using \(P(\phi)\) as the prior to compute a posterior \(P(\phi | Q)\) in an active learning setting.

In preliminary experiments, we compared the performance of this approach (termed 'Active'), interactions with random query generation (termed 'Random') and a heuristic query generation baseline (termed 'Base') based on modifying only the most likely formula in \(P(\phi)\). We also compared it against belief computed by directly providing the robot with just an equal number of demonstrations (termed 'Batch'). We conducted 200 simulated trials. For each trial, we sampled a ground truth formula and automatically generated demonstrations that satisfied it. The three query based models were initialized with \(P(\phi)\) generated using specification inference conditioned on two demonstrations. This was then followed by sequentially updating the belief as per the responses provided by the ground truth based oracle to the generated queries to yield \(P_{\text{final}}(\phi)\). In the 'Batch' case, the final posterior was generated conditioned on the same number of demonstrations as the total number data points in the query based cases. We compared the Entropy of final distribution indicating the confidence of the model, and the expected value of the similarity metric measured as an intersection-over-union of the clauses included in the candidate formula compared to the ground truth.

The results of the simulation experiment (Figure 2) indicate that both the 'Batch' and the 'Active' approach had the lowest entropy values compared to 'Base' and 'Random' indicating high confidence distributions. However the higher similarity score for the 'Active' approach indicates that it demonstrates better convergence to the true specification compared to 'Batch'. While the preliminary results are promising, we would like to repeat this experiment as a human-participant study where the participant provides both demonstrations and assessments. Besides the objective metrics evaluated here, we would also like to assess subjective measures for how well the participant’s perception of the robot’s competence aligns with the objective metrics.

5 CONCLUSION

In conclusion we propose an active learning framework that accepts user’s input through both demonstrations and query assessments for temporal tasks. Preliminary simulation experiments demonstrate the advantage of the interactive framework. We propose to conduct human-participant studies to further assess the interactive framework.
