ABSTRACT

We present an improved method for predicting the Sunyaev-Zeldovich (SZ) effect in galaxy clusters from spatially-resolved, spectroscopic X-ray data. Using the deprojected electron density and temperature profiles measured within a fraction of the virial radius, and assuming a Navarro, Frenk & White (1995) mass model, we show how the pressure profile of the X-ray gas can be extrapolated to large radii, allowing the Comptonization parameter profile for the cluster to be predicted precisely. We apply our method to Chandra observations of three X-ray luminous, dynamically relaxed clusters with published SZ data: RX J1347.5-1145, Abell 1835 and Abell 478. Combining the predicted and observed SZ signals, we determine improved estimates for the Hubble constant from each cluster and obtain a weighted mean of $H_0 = 69 \pm 8$ km s$^{-1}$ Mpc$^{-1}$ for a cosmology with $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$. This result is in good agreement with independent findings from the Hubble Key Project and the combination of cosmic microwave background and galaxy cluster data.

Key words: X-rays: galaxies: clusters – cosmic microwave background – cosmology: observations – distance scale – galaxies: clusters: individual (RX J1347.5-1145, Abell 1835, Abell 478)

1 INTRODUCTION

The inverse Compton scattering of cosmic microwave background (CMB) photons by hot electrons in galaxy clusters leads to a distortion of the CMB spectrum along the line of sight, known as the Sunyaev-Zeldovich (SZ, Sunyaev & Zeldovich 1972) effect. The magnitude of the SZ effect is determined by the Comptonization parameter of the cluster gas, $y(r)$, which is proportional to the line of sight integral of the gas pressure.

It was recognized swiftly (Silk & White 1978; Cavaliere, Danese & de Zotti 1979) that for an assumed, simple geometry, the combination of X-ray and SZ observations can be used to measure the angular diameter distance to a cluster. The ratio of the observed (based on radio/sub-mm observations) and predicted (based on X-ray observations) SZ signals is proportional to the square of the angular diameter distance, making this, potentially, an exceptionally powerful technique for probing the cosmic distance scale.

Although the SZ effect is now employed frequently to determine extragalactic distances (e.g., Mauskopf et al. 2001; Carlstrom et al. 2001; Mason, Myers & Readhead 2001; Jones et al. 2001; Reese et al. 2002), most studies to date have relied on the application of the $\beta$-model (Cavaliere & Fusco-Femiano 1978) in their X-ray analyses. The $\beta$-model provides a simple analytical approximation to the spatial distribution of the cluster gas. These studies have also generally assumed isothermality and relied on broad beam measurements of the mean, emission-weighted temperature when calculating the gas pressure.

With the Chandra X-ray Observatory and XMM-Newton it is now possible to measure the temperature, density and pressure profiles of the cluster gas precisely. The surface brightness distribution, in particular, can be resolved on sub-arcssecond scales. Chandra observations have shown that $\beta$-models do not, generally, provide good descriptions of the X-ray gas distributions in the cores of dynamically-relaxed clusters, and that the gas temperature is not isothermal but drops sharply within cluster cores (e.g., Schmidt et al. 2001; Allen et al. 2001; Kaastra et al. 2004). The main limitation of the new X-ray observations is that (due to background levels and restricted fields of view; $8 \times 8$ arcmin$^2$ for the Chandra ACIS-S detector) the gas temperature can only be measured directly out to radii $r \lesssim$ one third of the virial radius for most clusters. Since predictions of the SZ effect require the line-of-sight pressure integral through the clus-
ter, extrapolation of the X-ray results is therefore required for combined X-ray/SZ work.

In this paper we present a recipe for calculating the predicted SZ effect in clusters which makes use of the spatially-resolved spectroscopic techniques described in our earlier work, and which includes a new method for extrapolating the X-ray pressure profiles beyond the directly observed region. Analytical formulae for the electron density and temperature profiles of the X-ray gas at large radii are obtained under the assumption of hydrostatic equilibrium. These can be computed easily and used for SZ analysis. We show that our method, which takes full account of the observed density and temperature profiles of the X-ray emitting gas, provides a significant improvement in accuracy with respect to the standard isothermal $\beta$-model.

The outline of this paper is as follows: In Section 2 we review the standard $\beta$-model approach and describe our improved method. In Section 3 we apply our method to Chandra X-ray and SZ observations of three highly X-ray luminous, dynamically relaxed galaxy clusters: RX J1347.5-1145 ($z = 0.451$), Abell 1835 ($z = 0.2523$) and Abell 478 ($z = 0.088$). In Section 4 we use the combined data to measure the Hubble Constant. In Section 5 we compare our results to those obtained using the standard isothermal $\beta$-model approach. A summary of the results can be found in Sect. 6.

Unless stated otherwise, all quantities are quoted for a Hubble constant $H_0 = 70 \, \text{km} \, \text{s}^{-1} \, \text{Mpc}^{-1}$, matter density $\Omega_m = 0.3$ and vacuum energy density $\Omega_{\Lambda} = 0.7$. Error bars correspond to 1 $\sigma$ (68.3%) confidence.

2 PREDICTING THE SZ EFFECT

2.1 The standard $\beta$-model approach

Within the context of the isothermal $\beta$-model (Cavaliere & Fusco-Femiano 1978), the surface brightness profile of a galaxy cluster can be written as

$$I(\theta) \propto \left[ 1 + \left( \frac{\theta}{\theta_{0}} \right)^2 \right]^{-3 \beta + \frac{1}{2}},$$

(1)

where $\theta_0$ is the angular core radius and $\beta$ is the slope parameter. By calculating the X-ray emission due to hot cluster gas at a temperature $T$ (e.g., Kaastra & Mewe 1993, Liedahl et al. 1995), one can invert this to yield the central electron density $n_e(0)$ of the corresponding intrinsic (3-dimensional) electron density profile

$$n_e(r) = n_e(0) \left[ 1 + \left( \frac{r}{r_c} \right)^2 \right]^{-\frac{3\beta}{2}},$$

(2)

where the core radius $r_c$ follows from the angular diameter distance $d$ of the cluster, $r_c = d \times \theta_0$.

The Comptonization parameter along a line of sight at an impact parameter $R$ is defined by

$$y(R) = \int_{R}^{\infty} \frac{n_e(r) T(r)}{\sqrt{r^2 - R^2}} r \, dr$$

(3)

(e.g., Birkinshaw 1994, where we have converted the equation into an integral along radius $r$). Here $\sigma_T$ is the Thomson cross-section, $k_B$ the Boltzmann constant, $c$ the speed of light, and $m_e$ the electron mass. Eq. (3) can be integrated analytically for the isothermal $\beta$-model (e.g., Birkinshaw 1994) to give

$$y(R) = y_0 \left[ 1 + \left( \frac{R}{r_c} \right)^2 \right]^{-\frac{3\beta}{2} + \frac{1}{2}},$$

(4)

with the normalization constant

$$y_0 = n_e(0) r_c \sigma_T \left( \frac{k_B T}{m_e c^2} \right) B \left( \frac{1}{2}, \frac{3\beta}{2} \right) - \frac{1}{2}$$

(5)

(Mauskopf et al. 2000), where $B(a, b) = \Gamma(a) \Gamma(b)/\Gamma(a + b)$ is the beta function.

In previous work, the temperature $T$ has usually been taken to be the mean emission-weighted temperature of the X-ray gas, determined with broad-beam instruments. However, as discussed in Section 1, observations with the Chandra and XMM-Newton satellites have shown that regular, dynamically relaxed galaxy clusters are not isothermal. This temperature variation should be accounted for in the analysis.\footnote{Uncertainties in the determination of the distance scale associated with the assumption of isothermality were previously discussed by, e.g., Inagaki, Sugino-hara, & Suto 1993 and Yoshikawa et al. 1998.}

Finally, clusters are not infinitely large, as is usually assumed when calculating the predicted Comptonization parameter profile using the $\beta$-model. In what follows we show how modern X-ray data can be used to integrate eq. (3) without the assumption of isothermality, taking account of the finite size of galaxy clusters. In particular, where the region of the cluster directly observed in X-rays is small, the use of an extrapolation procedure like the one described here can become important.

2.2 An improved approach

2.2.1 Discretization of the $y$-parameter calculation

In order to calculate the expected $y$-parameter profile (eq. 3) for a particular galaxy cluster, the temperature profile $T(r)$ and the electron density profile $n_e(r)$ need to be known. In practice, deprojection analyses of Chandra or XMM-Newton data (e.g., Schmidt et al. 2001 and references therein) provide the electron density and X-ray gas temperature in $N$ discrete shells, with inner and outer radii $R_{in,i}$ and $R_{out,i}$, respectively. We can thus recast eq. (3) into a sum starting with shell $j$ at impact parameter $R$:

$$y(R) = \frac{2 \sigma_T k_B}{m_e c^2} \left( n_e(r) T(r) \right) \sqrt{r^2 - R^2} + \sum_{i=j+1}^{N} n_e(i) T_i \left( \sqrt{r^2 - R^2} - \sqrt{r_{out,i}^2 - R^2} \right).$$

(6)

For clusters with temperatures above about 8 keV, relativistic corrections also become significant. Analytic and fitting relations for the relativistic corrections to the SZ effect have been worked out by several groups: Itoh, Kodama & Nozawa (1998); Challinor & Lasenby (1998); Sazonov & Sunyaev (1998). Using the analytical formulae of Challinor & Lasenby (1998) up to second order, we determine the relativistic correction factor $\chi$.
that needs to be applied to each summand of $\Delta y_i$, so that $\Delta y_i \rightarrow \chi(T_i) \times \Delta y_i$.

2.2.2 Extrapolation of the temperature and gas density profiles

In the case of the Chandra X-ray Observatory, the detector size and the particle background limit the regions of clusters for which direct temperature measurements can be made ($r \leq r_1$) to a fraction of the virial radius. In order to calculate the predicted Comptonization parameter precisely, we need to extrapolate the temperature and electron density profiles out to the edge of the cluster, $r_2$ - or at least past the point where significant contributions to $y(r)$ are made. Here, for convenience, we will set $r_1 = r_{2500}$ and $r_2 = r_{200}$ (corresponding to the radii within which the mean enclosed mass density is $\Delta = 2500$ and $\Delta = 200$ times the critical density of the Universe $\rho_{crit}(z)$ at redshift $z$, respectively). $r_{2500}$ is typical of the outer radii for which useful information on the gas temperature profile can be obtained from Chandra observations. $r_{200}$ is used to mark the outer edge of the cluster. (In Sect. 2 we shall show that the precise choice of $r_2$ does not affect the results significantly.)

We parametrize the total mass distributions in the clusters using an NFW model

$$\rho(r) = \frac{\rho_{crit}(z) \delta_c}{(r/r_s) (1 + r/r_s)^2},$$

(7)

where $\rho(r)$ is the mass density, $r_s$ is the scale radius, $\rho_{crit} = \frac{3H(z)^2}{8\pi G}$, $H(z)$ is the Hubble constant, $G$ is the gravitational constant, $\delta_c = \frac{200}{\ln(1+z) - c_f/(1+c_f)}$, and $c$ is the concentration parameter with $c = r_{200}/r_s$. The temperature $T(r_1)$, electron density $n_e(r_1)$, and gas mass-weighted temperature $T_{m_1}$ within $r_1$ are assumed to be known from direct spatially-resolved spectroscopy. We extrapolate the electron density from $r_1$ to $r_2$ using a power-law model $n_e(r) \sim r^{-\gamma}$. The hydrostatic equation is then used to determine the temperature solution $T(r)$ for that power-law electron density profile in the given NFW potential (see Appendix A).

We fit the exponent $\gamma$ of the electron density profile so that the model complies with two fixed quantities:

(i) the observed temperature $T(r_1)$ at $r_1$

(ii) the gas-mass weighted temperature $T_{m_1}$ at $r_2$.

The power-law model approximates the true electron density profile between $r_1$ and $r_2$. (It is assumed that the galaxy cluster ends at $r_2$.) To determine the gas-mass weighted temperature $T_{m_1}$ within $r_2$, we use the solution for the radial dependence of the ratio of kinetic energy $W_{kin}$ and potential energy $W_{pot}$ in an NFW potential with an isotropic velocity dispersion. The key assumption here is that the gas-mass weighted temperature $T_{m_1}$ inside a radius $r$ is proportional to the kinetic energy of the mass distribution inside this radius (e.g., Eke et al. 1998). We then calculate the change, $q$, of the ratio $W_{kin}/W_{pot}$ between $r_1$ and $r_2$ as

$$q = \frac{W_{kin}(r_1)/W_{pot}(r_1)}{W_{kin}(r_2)/W_{pot}(r_2)} \frac{T_{m_1}(r_1)/T_{m_1}(r_1)}{T_{m_2}(r_2)/T_{m_2}(r_2)},$$

(8)

where $M_{tot}(r)$ is the total enclosed mass within radius $r$. The quantity $q$ can be computed as a function of the scale radius $r_s$ and the concentration parameter $c$ of the NFW profile using the analytical formulae included in Appendix A.

Thus, given both the gas-mass weighted temperature $T_{m_1}$ at $r_1$ and a specific NFW mass model from the Chandra data, the gas-mass weighted temperature $T_{m_1}$ at $r_2$ can be obtained from eq. (8). For the correct electron density slope $\gamma$, this is equal to the temperature that follows from the temperature solution (eq. (3)) and gas density profile $\rho_e(r)$ (for which we assume $\rho_e(r) = 1.1345 m_p n_e(r)$) via the integral

$$T_{m_1} = \frac{1}{M_{tot}} \int_{r_1}^{r_2} T(r) \rho_e(r) r^2 dr,$$

(9)

where $M_{tot}$ is the gas mass inside the radius $r$.

We note that in cases where the X-ray data only extend to radii $r_0 \ll r_{2500}$ (within which cooling and/or heating effects may have modified $T_{m_0}$ significantly), one should extrapolate the gas density (Appendix A) from $r_0$ to $r_{200}$, use this extrapolation to estimate the gas temperature and density at $r_1 = r_{2500}$, and then apply eq. (5) between $r_{2500}$ and $r_{200}$ as usual. (This is possible because the extrapolation recipe is attached continuously to the Chandra data so that $T_{m_1}$ can be calculated for any exponent $\gamma$ of the electron density extrapolation, regardless of where we attach the extrapolation.) We show below that this approach leads to robust answers in the case of Chandra observations of Abell 478, where the data cover only a relatively small radial range.

### Table 1. Details of the Chandra NFW mass models

| Object      | redshift | c                  | $r_s$ (Mpc) |
|-------------|----------|--------------------|-------------|
| RX J1347.5-1145 | 0.451    | $6.34^{+1.61}_{-1.36}$ | $0.37^{+0.18}_{-0.12}$ |
| Abell 1835  | 0.2523   | $4.21^{+0.53}_{-0.61}$ | $0.55^{+0.09}_{-0.12}$ |
| Abell 478   | 0.088    | $3.85^{+0.28}_{-0.36}$ | $0.61^{+0.07}_{-0.06}$ |

3 APPLICATION TO PUBLISHED CHANDRA AND SZ OBSERVATIONS

In this section we apply our method to Chandra and SZ observations of three galaxy clusters: RX J1347.5-1145, Abell 1835 and Abell 478. The X-ray data were originally published by Allen et al. (2002), Schmidt et al. (2001) and Sun et al. (2003), respectively.

3.1 Analysis of the X-ray data

Inside the region accessible to Chandra, the deprojected temperature and electron density profiles for the X-ray gas can be determined directly (under the assumption of spherical symmetry) using the methods described by Allen et al. (2001) and Schmidt et al. (2001). These data are then used to calculate the 68 per cent (1σ) confidence region of NFW mass models that provide the best-fit to the Chandra data. The results on the NFW mass models for RX J1347.5-1145, Abell 1835 and Abell 478 are summarized in Tab. 1.

We have carried out the extrapolation procedure described in Sect. 2 for every mass model within the 68% confidence region obtained for each cluster. The radii $r_1$ and
Figure 1. Extrapolated temperature and electron density profiles for RX J1347.5-1145, Abell 1835 and Abell 478. The best fit profiles are indicated by the solid lines. The upper and lower envelopes of the model ranges are plotted with dashed lines. For clarity we have only plotted the profiles up to the smallest \( \Delta = 200 \) overdensity radius of each model ensemble (see Tab. 2).

Table 2. Details of the cluster model extrapolation

| Object          | \( r_1 \) (Mpc) | \( r_2 \) (Mpc) | \( T(r_1) \) (keV) | \( T_{m,r_2} \) (keV) | \( n_e(r_1) \) \(\times 10^{-4} \) cm\(^{-3}\) | \( q \) | \( \gamma \) |
|-----------------|-----------------|-----------------|-------------------|-------------------|--------------------------|-----|------|
| RX J1347.5-1145 | 0.73±0.08       | 2.34±0.40       | 12.13±1.46        | 9.69±1.18         | 8.44±0.82                | 1.25±0.06 | 2.56±0.97 |
| Abell 1835      | 0.67±0.03       | 2.36±0.26       | 11.34±0.20        | 7.97±0.75         | 7.46±0.81                | 1.36±0.04 | 1.88±0.39 |
| Abell 478       | 0.66±0.03       | 2.36±0.18       | 8.29±0.16         | 6.41±0.32         | 5.92±0.60                | 1.40±0.04 | 1.90±0.09 |

\( r_2 \), the temperature \( T_{r_1} \), the ratio \( q \) (eq. 8) calculated using the formulae in Lokas & Mamon (2001) and the effective power-law exponent \( \gamma \) of the electron density distribution for the clusters are given in Tab. 2. In the case of Abell 478, the Chandra data do not extend beyond \( r \sim 0.3\,h^{-1}_{70} \) Mpc (corresponding to an overdensity \( \Delta = 8500 \)). Within this radius radiative cooling may have affected the observed temperature of the cluster gas. Following the instructions from Sect. 2.2.2 for such a case, the temperature profile and electron density profiles were extrapolated from \( r_{8500} \), but the exponent \( \gamma \) was determined using eq. (8) between \( r_{2500} \) and \( r_{200} \).

The application of our extrapolation procedure leads to the temperature and electron density profiles shown in Fig. 1. In this figure, both the best-fit profile and allowed range of models are shown. Note that the small scatter in the electron density profiles is a consequence of the small scatter in the luminosity profile derived from the Chandra data. The temperature profiles have been binned using a simple emission-weighting scheme.

For Abell 478, it is also possible to determine the power-law slope of the electron density distribution beyond \( r_1 \) using ROSAT observations (Allen 2000). Fitting the ROSAT data between 0.3 Mpc and 0.9 Mpc yields a slope of \( \gamma = 1.84 \pm 0.07 \). This result is consistent with our model predictions given the expected steepening of the profile beyond the limit of the ROSAT data.

Finally, we note that the power-law model used in extrapolating the density profile provides only an approximation to the density values at large radii. (The true profile will steepen with increasing radius.) However, the pressure profile – the relevant quantity for predicting the Comptoniza-
3.2 Combination with the SZ data

3.2.1 RX J1347.5-1145

Detections of the SZ effect in RX J1347.5-1145 were published by Pointecouteau et al. (2001, P01) at 142.9 GHz, Komatsu et al. (2001) at 21 GHz and 150 GHz and Reese et al. (2002) at 30 GHz using the Diabolo, Nobeyama and Owens Valley Radio Observatory (OVRO) instruments, respectively. The Comptonization parameters of all groups are consistent with each other. We compare the Chandra prediction with the Diabolo detection, which has the smaller beam size at 142.9 GHz of the two bolometers (Diabolo and Nobeyama), as well as a smaller error bar on the central Comptonization parameter than the OVRO interferometer result. P01 also published the flux decrement of the background radiation in four quadrants, which allows us to exclude the south-east quadrant, which contains hot, probably shocked, gas (Komatsu et al. 2001; Allen et al. 2002). Recently, Kitayama et al. (2004) have also carried out a detailed study of the intracluster medium in RX J1347.5-1145 using SZ observations. They obtain results in good agreement with those determined from the Chandra X-ray data.

In order to avoid the complicating effects of the shocked gas to the south-east of the cluster centre in RXJ1347-1145, only data from the other three quadrants were used to determine the X-ray mass model (Allen et al. 2002). P01 published the flux decrements in the four quadrants, excluding a small 16.2 arcsec × 16.2 arcsec square region around the nucleus (to avoid contamination by the central radio source). Adding all four quadrants, they find flux decrement of (39.0 ± 2.8) mJy in a square 100 arcmin × 100 arcmin area around the cluster centre. However, this becomes (26.8 ± 2.4) mJy once the south-east quadrant is excluded. This is the measurement we use for comparison with the X-ray data.

The intensity change ∆I due to the SZ effect can be calculated from the Chandra model. In the Kompaneets approximation (e.g. Birkinshaw 1994) this is given by

\[ \Delta I = I_0 y g(x) \] (10)

where \( I_0 = 2(k_B T_0)^3/h^2c^2 \),

\[ g(x) = \frac{x^4 e^x}{(e^x - 1)^2} \left[ \frac{x(e^x + 1)}{e^x + 1} - 1 \right] \] (11)

and \( x = h\nu/k_BT_0 \) with the Planck constant \( h \), observing frequency \( \nu \) and microwave background temperature \( T_0 \). Where relativistic corrections are significant, the Comptonization parameter \( y \) has to be modified appropriately (Sect. 2.2.1).

3.2.2 Abell 1835

The detection of the SZ effect in Abell 1835 was published by Mauskopf et al. (2000, M00) using the Suzie I and Suzie II bolometers. R02 have also published a detection using the OVRO interferometer at 30 GHz, which provides a consistent, but more precise determination of the Comptonization parameter. Here we compare our Chandra comptonization profiles with the co-added SuZIE I scans published by M00, using their \( \phi = -0.1 \) arcsec offset of the X-ray cluster centre from the scan centre. To calculate their difference channels D3 (two beams separated by 4.6 arcmin) and T123 (triple beam chop of three beams separated by 2.3 arcmin) of the bolometer array we followed the description given by M00.

3.2.3 Abell 478

Abell 478 was observed by Myers et al. (1997) at 32 GHz and reanalysed by Mason et al. (2001, MMR). The observed decrement was published as an average \( y \)-parameter \( y = 7.52 \pm 0.56 \times 10^{-5} \) within the telescope beam. Note that we use their value without the relativistic correction, as we apply this correction to the X-ray model. We compare the observed SZ decrement with the Chandra prediction using the beam switching technique described by Myers et al. (1997).

4 HUBBLE CONSTANT DETERMINATION

The Comptonization parameter \( y \) defined in eq. 3 depends upon the square root of the angular diameter distance to the cluster (Silk & White 1978; Cavaliere et al. 1979). By comparing the observed Comptonization parameter, \( y_{\text{obs}} \), within a given beam or aperture with the predicted value, \( y_{\text{pred}} \), from the X-ray data (for a given cosmology with \( H_0 = 70 \) km s\(^{-1}\) Mpc\(^{-1}\)), we can measure the Hubble constant e.g. (MMR),

\[ H_0 = \left( \frac{y_{\text{pred}}}{y_{\text{obs}}} \right)^2 \times 70 \text{ km s}^{-1} \text{ Mpc}^{-1}. \] (12)

Since eq. (10) is linear in the Comptonization parameter, these considerations also apply to the flux decrement \( \Delta F_\nu = \omega \Delta I_\nu \) (Sect. 2.2), where \( \omega \) is the solid angle of the emitting area, and \( \Delta I_\nu \) is the intensity decrement.

In order to compare our X-ray-predicted Comptonization parameter profiles with the direct SZ observations, we have convolved the X-ray profiles with the instrument beams for RX J1347.5-1145 (22 arcsec FWHM beam) and Abell 478 (7.35 arcmin FWHM beam and 22.16 arcmin beam switching as described by Myers et al. (1997)). For Abell 1835 we have added an additional normalisation parameter to the NFW parameter space of scale radius and concentration parameter constrained by the Chandra data (Table 1). To determine the best fit value and 1σ error for this normalisation parameter we added the \( \chi^2 \) contribution from the SuZIE I co-added scans (1.7 arcmin FWHM beam and 2.3 arcmin or 4.6 arcmin beam separation) to the \( \chi^2 \) contribution from the Chandra data. The normalisation parameter directly measures the distance scale and is represented here by the resulting Hubble constant.

The results for the three galaxy clusters are shown in Table 3. For quantities with two-sided error bars, the root-mean-square error was used to determine the error on the Hubble constant. The weighted mean of the three Hubble constant determinations in Table 3 is \( H_0 = 69 \pm 8 \) km s\(^{-1}\) Mpc\(^{-1}\).
Table 3. Results: Column two lists the observed quantity used to measure the Hubble constant. Columns three and four contain the measured and predicted values. The fifth column lists the observed areas. Column six contains the implied Hubble constant ($\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$).

5 COMPARISON WITH THE $\beta$-MODEL AND PREVIOUS STUDIES

As the method for calculating the predicted Comptonization profiles presented here is significantly different from the standard isothermal $\beta$-model approach, it is instructive to compare the results on $y(r)$ and the Hubble constant obtained with the two approaches.

We have fitted the Chandra surface brightness profiles with a $\beta$-model (eq. 11) inside a radius of 2.5 arcmin for RX J1347.5-1145, 3 arcmin for Abell 1835, and between radii of 1.5 arcmin and 4.5 arcmin for Abell 478. Note that in the case of Abell 478 the core of the cluster had to be excluded, because the central surface brightness profile is not flat, as is required by the $\beta$-model. The mean, emission-weighted temperatures from single-temperature fits to the Chandra spectra and the $\beta$-model parameters are given in Tab. 4.

The temperatures were determined using the MEKAL (Kaastra & Mewe 1993; Liedahl et al. 1995) plasma model. The gas density normalization $n_{e,0}$ was calculated from the surface brightness using the MEKAL plasma emission model with the spectrally determined metallicities. Relativistic corrections were applied as described in Sect. 2.2.1.

Using eq. 11, together with the appropriate relativistic correction factors, we obtain the central Comptonization parameters $y_0 = 1.13 \times 10^{-3}$ for RX J1347.5-1145, $y_0 = 4.2 \times 10^{-4}$ for Abell 1835 and $y_0 = 3.5 \times 10^{-4}$ for Abell 478.

Fig. 2 shows the best-fit Comptonization parameter profiles determined with our new method (solid line) together with the results from the standard isothermal $\beta$-model approach (dashed line). This plot shows that the Comptonization parameter profiles for the $\beta$-model differ substantially from the profiles obtained using the new, deprojected/extrapolated solution. Firstly, the overall normalization in the core can be quite different. Secondly, the slope of the $\beta$-model is too shallow at large radii due to the infinite extent assumed in that model. (We note that the $\beta$-model can yield significantly different answers when applied to other data sets covering different ranges of radii (Pointecouteau et al. 2001; Reese et al. 2002; Mason et al. 2003). Here we have applied the two approaches to the same Chandra data simply to enable a direct comparison of the methods on the basis of the same, well-defined data sets.)

Applying the procedure described in Sect. 4 to the measured $\beta$-profile parameters yields Hubble constant estimates of $H_0 = 32$ km s$^{-1}$ Mpc$^{-1}$ for RX J1347.5-1145, $H_0 = 29$ km s$^{-1}$ Mpc$^{-1}$ for Abell 1835 and $H_0 = 103$ km s$^{-1}$ Mpc$^{-1}$ for Abell 478. One can immediately see that the application of the isothermal $\beta$-model does not yield a consistent estimate when applied naively to Chandra data for the present sample of clusters.

It is also interesting to compare these estimates with previously published $\beta$-model estimates for the clusters discussed here. We have translated the electron densities from other studies into our assumed cosmology ($\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$ and $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$).

RX J1347.5-1145: P01 determined a Hubble constant $H_0 = 44 \pm 6$ km s$^{-1}$ Mpc$^{-1}$ using a $kT = 9.3$ keV isothermal model with the $\beta$-model parameters $\theta_\epsilon = 8.4$ arcsec, $\beta = 0.56$ and $n_{e,0} = 0.102$ cm$^{-3}$ from ROSAT (Schindler et al. 1997). Using the same temperature and a slightly different $\beta$-model, R02 found an angular diameter distance that implies $H_0 = 68.2^{+26.8}_{-15.5}$ km s$^{-1}$ Mpc$^{-1}$. This estimate is consistent with the value we obtain using our fully deprojected and extrapolated cluster model (Tab. 4). However, the gas temperature and the other $\beta$-model parameters used by R02...
are not consistent with the β-model parameters from Chandra (Tab. 4).

**Abell 1835:** For this cluster, M00 measured a Hubble constant \( H_0 = 66^{+38}_{-22} \) km s\(^{-1}\) Mpc\(^{-1}\) for a \( kT = 9.8 \) keV isothermal model with the β-model parameters \( \theta_c = 13.2 \) arcsec, \( \beta = 0.58 \) and \( n_{e0} = 0.058 \) cm\(^{-3}\) from a fit to ROSAT data. This temperature was obtained by allowing for a cooling flow component in the core of the cluster. R02 obtained an angular diameter distance to the cluster which implies \( H_0 = 55.4^{+13.2}_{-8.8} \) km s\(^{-1}\) Mpc\(^{-1}\), based on a \( kT = 8.21 \) keV isothermal model (no cooling flow correction). The difference between these two measurements can be attributed to the different isothermal temperatures and small differences in the assumed β-model parameters. Note also that the β-model parameters used in these studies are significantly different from those determined from Chandra (Tab. 4) over a smaller range of radii. This explains the difference in the predicted Hubble constant. However, the M00 result is consistent with the result we obtain from the deprojected and extrapolated X-ray data, which shows that it is possible to partially correct the β-model in the central region of the cluster when the surface brightness profile observed with the ROSAT field of view is used. For larger radii this approximation will fail, however, because of the fixed β-model slope.

**Abell 478:** MMR measured a Hubble constant \( H_0 = 61^{+34}_{-21} \) km s\(^{-1}\) Mpc\(^{-1}\) assuming an isothermal \( kT = 8.4 \) keV model with the β-model parameters \( \theta_c = 1 \) arcmin, \( \beta = 0.64 \) and \( n_{e0} = 0.023 \) cm\(^{-3}\) from ROSAT. This temperature also accounts for the presence of a cooling flow in the cluster core. Sun et al. (2003) improved upon the result by MMR by determining the Comptonization parameter as a function of radius from a depopjection of the Chandra data, and by extrapolating the Chandra data with a β-model based on a fit to the combined surface brightness profile from Chandra and ROSAT. They used \( \beta = 0.68 \) and obtained a Hubble constant estimate \( H_0 = 64^{+13}_{-15} \) km s\(^{-1}\) Mpc\(^{-1}\), which lies between our value and the one obtained by MMR.

### 6 SUMMARY AND DISCUSSION

We have presented a new method for extrapolating the pressure profiles of galaxy clusters beyond the region accessible to current X-ray satellites such as Chandra and XMM-Newton, for use in combined X-ray and SZ studies. Our method assumes hydrostatic equilibrium, an NFW mass profile for the clusters and predicts the temperature profile and an effective power-law slope of the electron density profile. The method does not assume isothermality and provides a simple extrapolation recipe that can be easily implemented. We have applied our method to the Chandra data for three X-ray bright, dynamically relaxed galaxy clusters, RX J1347.5-1145, Abell 1835 and Abell 478, and have obtained detailed temperature, electron density and Comptonization parameter profiles for these clusters out to the virial radius.

Since all three clusters have published SZ detections, we were also able to measure the Hubble constant for each, as shown in Table 4. The individual measurements are consistent with each other and yield a weighted mean of \( H_0 = 69 \pm 8 \) km s\(^{-1}\) Mpc\(^{-1}\). This result is consistent with findings from the Hubble Key Project (\( H_0 = 72 \pm 8 \) km s\(^{-1}\) Mpc\(^{-1}\); Freedman et al. 2001) and combined studies of the cosmic microwave background and X-ray galaxy cluster data (\( H_0 = 68.4^{+2.4}_{-1.4} \) km s\(^{-1}\) Mpc\(^{-1}\); Allen, Schmidt & Bridle 2003). Note that our weighted mean value does not include additional systematical errors, due to, e.g., clumping or asphericity, although for such regular, relaxed clusters these should be at a minimum.

The contribution to the predicted Comptonization parameter from material beyond the regions directly observed with Chandra, modelled by our extrapolation procedure, varies from system to system. For RX J1347.5-1145 the correction to the Comptonization parameter in the region used in Table 3 amounts only to 1 per cent and is negligible. For Abell 1835, however, the contribution from material in the extrapolated region amounts to 20 per cent, and for Abell 478 the contribution rises to 68 per cent. This shows that a robust extrapolation method is necessary when combining X-ray and SZ observations to infer cosmological information.

We have estimated the effect of changing the outer radius \( r_{200} \) by repeating the calculation for Abell 478, but stopping at \( r_{500} \). This leads to a 4.2 per cent smaller average Comptonization parameter, well within the observational error bar.

We have compared the Comptonization parameter profiles predicted by our method with the profiles obtained by fitting an isothermal β-model to the Chandra data. We find that a naive application of the β-model approach leads to profiles with significantly different central Comptonization parameters and predicts different slopes for the Comptonization parameter profiles at large radii. The isothermal β-model also leads to inconsistent Hubble constant estimates when applied to the Chandra data sets considered here.

It is clear that for galaxy clusters like Abell 478, a field of view larger than the one afforded by the Chandra ACIS-S3 detector would be beneficial. In this respect the combination of Chandra and XMM-Newton observations will help (e.g. Pointecouteau et al. 2004), although the detector background will still prohibit precise measurements of the temperature profile beyond \( r \sim 0.5r_{200} \). (We also note that the high spatial resolution of Chandra is important in resolving the central temperature profile and constraining the best-fit NFW mass models.)

Observations for a larger sample of clusters, as well as deeper X-ray and SZ observations, should make this a powerful method to explore the cosmological distance scale. In the first case, it will be important to concentrate such studies on the largest, dynamically relaxed clusters for which systematic uncertainties associated with the deprojection method and assumption of hydrostatic equilibrium are at a minimum.

APPENDIX A: AN EXTRAPOLATION SOLUTION FOR THE X-RAY GAS TEMPERATURE PROFILE IN AN NFW POTENTIAL

Let the mass distribution of a galaxy cluster be parametrized by a NFW mass model (eq. 7). Also, let the electron density distribution be determined for a certain range of radii be parametrized by a power-law model

\[ n_e(r) \sim r^{-\gamma}. \]  

(A1)

The temperature as a function of radius can then be determined under the assumption of hydrostatic equilibrium by solving the hydrostatic equation

\[ \frac{d(n_e kT)}{dr} = -\mu m_p \frac{GM}{r^2}. \]  

(A2)

where \( k \) is the Boltzmann constant, \( \mu \) is the molecular weight of the gas and \( m_p \) is the proton mass (note that the normalization of (A1) drops out of this equation). Using the method of the variation of the constant one finds that is possible to write the solution of (A2) in the form

\[ kT(r) = \left( \frac{r}{r_1} \right)^\gamma \left( kT_1 - \frac{4\pi r_1^2 \Delta \rho \mu m_p G}{(1 + \gamma)} r_1^{1+\gamma} \times \right. \]

\[ \left. \left( r r_1^{1+\gamma} f_1(-\gamma, 1; 1 - \gamma; -\frac{r}{r_2}) - r_1 r_1^{1+\gamma} f_1(-\gamma, 1; 1 - \gamma; -\frac{r}{r_2}) \right. \right. \]

\[ \left. \left. - r_2 r_1^{1+\gamma} \ln \left( 1 + \frac{r}{r_2} \right) + r_2 r_1^{1+\gamma} \ln \left( 1 + \frac{1}{r_2} \right) \right) \right) \]  

with the boundary condition \( T(r_1) = T_1 \). \( f_1 \) is the hypergeometric function (e.g., Gradshteyn & Ryzhik 2000, p. 995) which is well-defined on the whole negative real axis and is available in standard mathematical packages.

APPENDIX B: THE ENERGY DISTRIBUTION OF THE NFW MASS DISTRIBUTION

In this Appendix we list the (Lokas & Mamon 2001) expressions for the potential energy \( W_{pot} \) and the kinetic energy \( W_{kin} \) in an NFW potential with an isotropic velocity dispersion, as a function of radius \( r \). The ratio of these quantities is used in Sect. 2.2.2 to determine the cluster model extrapolation. It can be calculated from the concentration parameter \( c \) and the scale radius \( r_s \).

The radial dependence of the potential energy associated with an NFW mass distribution with virial radius \( r_{200} = c \times r_s \) as a function of (scaled) radius \( s = \frac{r}{r_{200}} \) is

\[ W_{pot}(s) = - W_\infty \left[ 1 - \frac{1}{(1 + cs)^2} - \frac{2\ln(1 + cs)}{1 + cs} \right]. \]  

(B1)

(eq. 21 in Lokas & Mamon 2001), where \( W_\infty \) is the asymptotic value

\[ W_\infty = \frac{GM_0^2}{2c_s^2r_s}, \]  

(B2)

\[ \Delta \rho \] is the density contrast of the mass distribution.
The radial dependence of the kinetic energy, assuming isotropic velocity dispersion, is

\[
W_{\text{kin}}(s) = \frac{1}{2} W_\infty \left\{ -3 + \frac{3}{1 + cs} - 2 \ln(1 + cs) \\
+ cs[5 + 3 \ln(1 + cs)] - c^2 s^2[7 + 6 \ln(1 + cs)] \\
+ c^3 s^3 \pi^2 - \ln c - \ln s + \ln(1 + cs) \\
+ 3 \ln^2(1 + cs) + 6 \text{Li}_2(-cs) \right\}
\]

(eq. 24 in [Lokas & Mamon 2001]), where \( \text{Li}_2 \) is the dilogarithm.
