(Dated: March 23, 2022)

We present a simple and efficient method to optimize within energy minimization the determinantal component of the many-body wave functions commonly used in quantum Monte Carlo calculations. The approach obtains the optimal wave function as an approximate perturbative solution of an effective Hamiltonian iteratively constructed via Monte Carlo sampling. The effectiveness of the method as well as its ability to substantially improve the accuracy of quantum Monte Carlo calculations is demonstrated by optimizing a large number of parameters for the ground state of acetone and the difficult case of the $1^1B_{1u}$ state of hexatriene.

Over the last decade, quantum Monte Carlo (QMC) methods have been employed to accurately compute electronic properties of large molecular and solid systems where conventional quantum chemistry approaches are extremely difficult to apply. A crucial step in both the variational (VMC) and the diffusion Monte Carlo (DMC) approach is the construction of the trial wave function $\Psi_T$ which is usually chosen of the Jastrow-Slater form, that is $\Psi_T = J \Phi$, where $\Phi$ is a small expansion in Slater determinants and $J$ the positive Jastrow correlation factor.

Although considerable progress has been made (principally using the variance minimization approach) in the construction of optimal Jastrow factors, relatively little attention has been given to the optimization of the determinantal part of the wave function. Methods such as Hartree-Fock (HF) or a small scale configuration interaction (CI) are used as a practical way of constructing the determinantal component, which is generally not reoptimized when the Jastrow factor is added. However, the determinantal part of the wave function solely determines the DMC energy and often needs to be reoptimized to obtain accurate results. A practical and simple approach to calculate the optimal determinantal component is therefore particularly important to a wide and successful application of QMC methods.

In recent years, several methods to optimize the wave function through energy minimization have been proposed. A direct approach to energy minimization entails to compute the gradient and the Hessian of the energy with respect to the orbital parameters in the determinant. The use of an estimate of the Hessian characterized by reduced statistical fluctuations yields a simple and robust optimization algorithm for the Jastrow parameters. However, the Hessian with respect to the orbital parameters in the determinant is affected by higher statistical noise so that devising a stable energy-minimization scheme is more difficult: the resulting approach is for instance less stable that the simple stochastic reconfiguration (SR) method and, during the optimization, may have to reduce to the inefficient SR to retain stability. To date, the most successful method remains the energy fluctuation potential (EFP) method which determines the optimal determinantal component as the solution of an effective Hamiltonian iteratively constructed via Monte Carlo sampling. The approach has been used to optimize the orbitals, the linear coefficients in front of the determinants, and has been extended to excited states. The method is very stable and more efficient than the SR approach but quite complex: the construction of the starting effective Hamiltonian as well as its update are computationally very demanding steps, especially for large systems.

In this Letter, we propose a simple and efficient optimization method for the determinantal component of the wave function. The approach constructs the optimal wave function via a perturbative scheme based on the EFP method, and only requires easily accessible quantities from the quantum chemical calculation used to set up the starting wave function. The performance of the method is demonstrated on acetone and on the difficult case of the $1^1B_{1u}$ state of hexatriene. First, we will briefly review the EFP method.

The energy fluctuation potential method. Let us assume that the trial wave function $\Psi_T$ depends on a set of parameters $\{\alpha_k\}$. The derivatives of the energy with respect to the parameters can be written as:

$$\frac{\partial E}{\partial \alpha_k} = 2(\langle E_L - \bar{E} \rangle (O_k - \bar{O}_k)), \quad (1)$$

where $\langle \cdot \rangle$ denotes the average with respect to the square of the trial wave function $|\Psi_T|^2$, which can be computed by Monte Carlo sampling. We defined $\bar{E} = \langle E_L \rangle$ and $\bar{O}_k = \langle O_k \rangle$ where

$$E_L = \frac{H \Psi_T}{\Psi_T}, \quad \text{and} \quad O_k = \frac{1}{\Psi_T \partial \alpha_k} \frac{\partial \Psi_T}{\partial \alpha_k}. \quad (2)$$

For the optimal parameters, the derivatives of the energy (Eq. 1) are zero, and the fluctuations of the local energy $E_L$ and of the functions $O_k$ are uncorrelated. This means that the energy is stationary if the remaining fluctuations of the local energy cannot be further reduced by adding some combination of the functions $O_k$. Hence, the minimization of the energy can be reformulated as a least-squares fit of the fluctuations of the local energy with the
functions $O_k$:
\[ \chi^2 = \langle (E_L - V_0 - \sum_{k>0} V_k O_k)^2 \rangle, \] (3)

A minimization of $\chi^2$ with respect to the parameters $V_k$ leads to the following set of linear equations for $m > 0$:
\[ \langle \Delta E \Delta O_m \rangle = \sum_{k>0} V_k \langle \Delta O_k \Delta O_m \rangle \] (4)

where we have eliminated $V_0$ from the other equations, and $\Delta E = E_L - \bar{E}$ and $\Delta O_m = O_m - \bar{O}_m$. Since the left-hand side of these equations corresponds to the derivatives of the energy (Eq. 14), the fitting parameters $V_k$ are zero if and only if all the derivatives of the energy are zero. In general, the parameters $V_k$ which solve these linear equations will not be equal to zero and can be used to improve the current trial wave function $\Psi_T$.

We focus here on the EFP procedure to optimize the determinantal part $\Phi$ of the trial wave function $\Psi_T$:
\[ \Psi_T = J \Phi = J \sum_i c_i C_i, \] (5)

where a spin-adapted configuration state function (CSF) $C_i$ is a linear combination of Slater determinants $D_i$ of single-particle orbitals. Let us assume that the starting $\Phi$ is the lowest solution $\Phi^{(0)}_0$ of the CI Hamiltonian $\mathcal{H}^{(0)}$:
\[ \mathcal{H}^{(0)} = \sum_i E^{(0)}_i |\Phi^{(0)}_i\rangle \langle \Phi^{(0)}_i|, \] (6)

where the states $\Phi^{(0)}_i$ span the same space as the CSFs. To obtain the optimal coefficients $c_i$ or equivalently the best solution in the basis of the eigenstates of $\mathcal{H}^{(0)}$, we consider the variations of $\Phi$ with respect to the eigenstates other than $\Phi^{(0)}_0$:
\[ \Phi = \Phi^{(0)}_0 \rightarrow \Phi' = \Phi^{(0)}_0 + \sum_{k>0} \delta_k \Phi^{(0)}_k, \] (7)

so that $\delta_k = \Phi^{(0)}_k/\Phi^{(0)}_0$. The quantities appearing in the linear equations (Eq. 17) are sampled from $\Psi_T = J \Phi^{(0)}_0$ and parameters $V^{(0)}_k$ are used to construct a new Hamiltonian $\mathcal{H}^{(1)}$ as
\[ \mathcal{H}^{(1)} = \mathcal{H}^{(0)} + \sum_{k>0} V^{(0)}_k \left( \Phi^{(0)}_0 \langle \Phi^{(0)}_k | + h.c. \right). \] (8)

This Hamiltonian is diagonalized, yielding a new set of states, and the procedure is iterated until convergence.

If we also want to optimize the orbitals in the Slater determinants, we can linearize the problem using a so-called super-CI expansion to treat the CI and orbital variations on the same footing: the CSFs occupied in the wave function (Eq. 5) are augmented by all possible single excitations from the occupied to a set of external orbitals, and the occupied orbitals can be improved by using the natural orbitals of the CI wave function in this augmented space [13]. The EFP scheme to optimize the determinantal component via a super-CI approach [4] is quite complex. Setting up the starting super-CI Hamiltonian is not trivial, and the number of singly-excited CSFs increases with the number of CSFs in the reference wave function and with the size of the basis (i.e. with the number of available external orbitals) so that the approach quickly becomes computationally too demanding.

A simplified EFP approach. The basic idea of the scheme proposed here is to avoid the explicit construction of the EFP Hamiltonian by solving the problem perturbatively. For the example given above, we obtain an improved wave function (Eq. 7) not by diagonalizing the Hamiltonian (Eq. 8) but approximately, to first order in the perturbation given by the corrections $V^{(0)}_k$:
\[ \Phi = \Phi^{(0)}_0 \rightarrow \Phi' = \Phi^{(0)}_0 - \sum_{k>0} \frac{V^{(0)}_k}{E^{(0)}_k - E^{(0)}_0} \Phi^{(0)}_k. \] (9)

It is simple to show that, in the absence of the Jastrow factor, this is indeed the perturbative solution for $\mathcal{H} - \mathcal{H}^{(0)}$ since $V^{(0)}_k = \langle \Phi^{(0)}_k | \mathcal{H} - \mathcal{H}^{(0)} | \Phi^{(0)}_0 \rangle$. This perturbative EFP scheme can also be viewed as a generalization of the SR method [11, 12] which yields an improved wave function by applying the operator $\Lambda - \mathcal{H}$ to the current state and projecting the result onto the space defined by the parameterization. The SR wave function is constructed as in Eq. (9) but all the changes are scaled by the same energy denominator while the EFP approach scales each correction appropriately, achieving significantly faster convergence [4].

Estimate of the energy denominators. The perturbative solution of the EFP problem requires the knowledge of the energy denominators appearing in Eq. (9), which can be easily estimated with the use of quantities readily available from the quantum chemical calculation used to set up the starting wave function. We will first consider the optimization of the orbital parameters.

The simplest case is given by a trial wave function constructed from a single closed-shell determinant as $\Psi_T = JD_0$, where $D_0$ is a determinant of Hartree-Fock or density functional Kohn-Sham orbitals which we want to reoptimize in the presence of the Jastrow factor. We assume here that we have chosen HF orbitals but all the following considerations equally apply to the case of density functional orbitals. The set of occupied and virtual HF orbitals and the atomic basis on which they are expanded span the same space so that we can express the variations of one orbital with respect to the expansion coefficients in terms of the variations with respect to the other orbitals. To optimize the $M$ occupied orbitals $\varphi^i$ in $D_0$, we only need to consider the variations with respect
to the $N - M$ virtual orbitals as

$$\varphi_i \rightarrow \varphi'_i = \varphi_i + \sum_{j=M+1}^{N} c_{ij} \varphi_j,$$

(10)

where we only mix orbitals of the same symmetry. The corresponding first-order change in the wave function is

$$\Psi_T \rightarrow \Psi'_T = JD_0 + \sum_{i=1}^{M} \sum_{j=M+1}^{N} c_{ij} J C_{0}^{i,j},$$

(11)

where $C_{0}^{i,j} = D_{0}^{i,j} + D_{0}^{j,i}$ is the CSF of the two determinants obtained by substituting the orbital $\varphi_i$ with orbital $\varphi_j$ for the up and down spin, respectively. It is simple to show that $O^{i,j} = C_{0}^{i,j} / D_0$.

Following the EFP procedure, we sample from $\Psi_T$ the quantities appearing in the linear equations (Eq. 11) and obtain the corrections $V^{i,j}$ corresponding to the functions $O^{i,j}$. We can then obtain an improved determinantal component in analogy to Eq. (9) as

$$\Phi' = D_0 - \sum_{i=1}^{M} \sum_{j=M+1}^{N} \frac{V^{i,j}}{\Delta E^{i,j}} C_{0}^{i,j},$$

(12)

where we assign an energy scale $\Delta E^{i,j}$ to the variation corresponding to the single excitation $C_{0}^{i,j}$. We now make the key observation that, to first order, this is equivalent to the much simpler step of constructing an improved set of occupied single-particle orbitals as

$$\varphi'_i = \varphi_i - \sum_{j=M+1}^{N} \frac{V^{i,j}}{\Delta E^{i,j}} \varphi_j,$$

(13)

which can be used in a new single-determinant wave function $\Psi'_T = JD'_0$. We then proceed iteratively by sampling a new set of $V^{i,j}$ from the wave function $\Psi'_T$ and updating the orbitals as in Eq. (13) until convergence.

To estimate the energy denominators $\Delta E^{i,j}$, we note that the starting HF orbitals are canonical orbitals obtained by diagonalizing the Fock matrix so that the corresponding eigenvalues have a physical interpretation via the Koopman’s theorem. Minus the eigenvalues of the occupied and the virtual orbitals are an approximation to the ionization potentials (IP) and the electron affinities (EA), respectively. The energy associated to the promotion of one electron from orbital $\varphi_i$ to orbital $\varphi_j$ can therefore be estimated as the difference IP–EA, namely

$$\Delta E^{i,j} \sim E^{i,j} - E_{HF} \sim \epsilon_j - \epsilon_i,$$

(14)

where $\epsilon_i$ and $\epsilon_j$ are the eigenvalues corresponding to orbitals $\varphi_i$ and $\varphi_j$. We do not find it necessary at successive iterations to update the parameters $\Delta E^{i,j}$ which are therefore kept fixed at the starting HF values.

In Fig. 1 we compare the convergence of the proposed method, denoted by “perturbative EFP”, with the EFP and the SR methods for the orbital optimization of a single closed-shell Jastrow-Slater wave function for the ground state of acetone ($C_3H_6O$). To demonstrate the robustness of the method, we construct a poor starting determinantal component from a set of unconverged HF orbitals obtained by diagonalizing the Fock matrix built from the Hückel orbitals. A simple electron-electron and electron-nucleus Jastrow factor is employed and the 473 orbital parameters are optimized using the starting unconverged eigenvalues as estimates for the energy denominators (Eq. 11). The SR optimization is performed with the critical value of $\Lambda$ estimated as in Ref. 4, and converges to the optimal wave function only after 40 steps. The perturbative EFP approach converges in only 2 steps as the EFP method, with a computational effort as low as the one of the SR method. Interestingly, the perturbative method is successful even when using the eigenvalues of the starting Hückel orbitals to roughly estimate the energies $\Delta E^{i,j}$. Finally, if we start from converged HF orbitals, the energy gain from the optimization is of 14 ± 1 and 6 ± 1 mHartree in VMC and DMC, respectively.

The procedure is not very different if the wave function is constructed from a spin-unrestricted determinant. The variations of an occupied orbital (Eq. 10) are now with respect to the virtual orbitals of the same spin, and the excitation energies are estimated as $\Delta E^{i,\sigma,j,\sigma}$ with $\epsilon_i,\sigma - \epsilon_i,\sigma$ where $\sigma$ is the spin of the varied orbital. The case of a restricted open-shell determinant is instead more complicated since the final orbitals and eigenvalues of a restricted open-shell Hartree-Fock calculation are not uniquely defined. Among the many constructions available in the literature, we find that the one by Guest and Sauders [18] yields eigenvalues which, in average, well approximate the excitation energies in Eq. (11). Note that closed-to-open-shell excitations must also be included in Eq. (10) to allow full orbital variation.

For a multideterminant wave function from a complete-active-space self-consistent-field (CASSCF) calculation, a set of canonical orbitals is usually defined as diagonalizing the closed, active and virtual blocks of the so-called

![FIG. 1: Convergence of the VMC energy of acetone with the perturbative EFP, the EFP and the SR method to optimize the 473 orbital parameters. The starting determinantal component is from an unconverged HF calculation. The statistical errors are smaller than the symbol size.](image-url)
tively. Therefore, for these excitations, we follow Ref. 19

to estimate of the closed-shell-to-active and active-to-virtual

and 493 parameters for the ground and excited state, respectively.
The errors on the last figure are given in parenthesis.

However, to obtain a good estimate of the closed-shell-to-active and active-to-virtual
exitation energies, the eigenvalues must be properly ad-

for orbital and CI parameters and sample the quantities
in Eq. (15) for both variations. The corrections
for orbital and CI parameters and sample the quantities
in Eq. (15) for both variations. The corrections

where $\epsilon$ is a CASSCF eigenvalue, $\rho$ is the single-particle
density matrix, and $\lambda$ is an average difference between
the electron affinity and the ionization potential of the
active orbitals, chosen of the order of 0.3-0.5 Hartree.

Finally, we consider the simultaneous optimization of
orbitals and CI coefficients. The simplest approach is to
alternate between an orbital optimization step with the
perturbative EFP method, and a CI calculation in the
basis of the CSFs multiplied by the Jastrow factor $\tilde{S}$. Alternatively, we can use the perturbative EFP method
for orbital and CI parameters and sample the quantities
in Eq. (15) for both variations. The corrections $V_k$ for the
CI coefficients are computed in the basis of the CI states
obtained in a starting CI calculation, and the energy
denominators (Eq. 15) estimated using the CI energies.

In Table I, we demonstrate the performance of the method
on the $1^1B_{u}$ state of trans-hexatriene (C$_6$H$_6$) which represents a challenge for all electronic structure
approaches: CASPT2 yields a vertical excitation energy of only 5.01 eV [21] while the TDDFT energies range
between 4.42 and 4.64 eV, depending on the functional employed [22]. For the single-determinant closed-shell
ground state, the VMC energy is improved by about 7
mHartree when optimizing the HF orbitals while, differ-
ently from acetone, the DMC energy is not significantly
affected [23]. The excited state is mainly an excitation
from the highest occupied (LUMO) to the lowest unoccupied (HOMO) orbital and well described a two-
determinant singlet wave function. A CASSCF wave
