THE COMPUTATION OF DISCONNECTED BIFURCATION DIAGRAMS

P. E. FARRELL∗, C. H. L. BEENTJES†, AND Á. BIRKISSON‡

Abstract. Arclength continuation and branch switching are enormously successful algorithms for the computation of bifurcation diagrams. Nevertheless, their combination suffers from three significant disadvantages. The first is that they attempt to compute only the part of the diagram that is continuously connected to the initial data; disconnected branches are overlooked. The second is that the subproblems required (typically determinant calculation and nullspace construction) are expensive and hard to scale to very large discretizations. The third is that they can miss connected branches associated with nonsimple bifurcations, such as when an eigenvalue of even multiplicity crosses the origin. Without expert knowledge or lucky guesses, these techniques alone can paint an incomplete picture of the dynamics of a system.

In this paper we propose a new algorithm for computing bifurcation diagrams, called deflated continuation, that is capable of overcoming all three of these disadvantages. The algorithm combines classical continuation with a deflation technique that elegantly eliminates known branches from consideration, allowing the discovery of disconnected branches with Newton’s method. Deflated continuation does not rely on any device for detecting bifurcations and does not involve computing eigendecompositions; all subproblems required in deflated continuation can be solved efficiently if a good preconditioner is available for the underlying nonlinear problem. We prove sufficient conditions for the convergence of Newton’s method to multiple solutions from the same initial guess, providing insight into which unknown branches will be discovered. We illustrate the success of the method on several examples where standard techniques fail.

Key words. continuation, bifurcation, deflation, branch switching, deflated continuation.

1. Introduction. We consider numerical methods for computing the solutions of

\[ f(u, \lambda) = 0, \quad (1.1) \]

where \( f : U \times \mathbb{R} \to Y \) is the \( C^1 \) problem residual, \( U \) and \( Y \) are isomorphic Banach spaces, \( u \in U \) is referred to as the solution, and \( \lambda \in \mathbb{R} \) is referred to as the parameter. In our applications, (1.1) typically represents the residual of a stationary ordinary or partial differential equation, along with boundary conditions. The associated bifurcation diagram visualizes how the behaviour of a functional of the solutions changes as \( \lambda \) is varied over some interval of interest \([\lambda_{\min}, \lambda_{\max}]\).

Arclength continuation and branch switching \([17, 10, 15, 8, 27]\) are central techniques in the computational analysis of (1.1) and are routinely used throughout science and engineering. Given an initial point \((u_0, \lambda_0)\) on a branch, arclength continuation (or its popular variant, pseudo-arclength continuation) robustly traces out the remainder of that branch. It parameterizes the solution and parameter \((u(s), \lambda(s))\) as

Branch switching algorithms attempt to detect bifurcation points along a branch and to construct initial solutions on the branches emanating from it, Figure 1.1. The detection step typically relies on the computation of the bifurcation test functional

\[ \tau(u, \lambda) = \text{sign} \left( \det J(u, \lambda) \right) = \text{sign} \left( \prod_i \mu_i(u, \lambda) \right), \]  

(1.2)

where \( \mu_i \) are the eigenvalues of the (discretized) Jacobian \( J \), including multiplicities. This test functional is cheaply computable if an LU decomposition of \( J \) is already available from a continuation step [27], but is very difficult to estimate if a Krylov method is used. Once a bifurcation point has been identified, initial guesses for solutions on the emanating branches are constructed from the nullspace of \( J \) there. Once one solution on each emanating branch is known, arclength continuation is used to complete the branch. Henceforth, this combination of arclength continuation and branch switching will be referred to as switching continuation.

Switching continuation computes fragments of bifurcation diagrams: it attempts to compute the part of the bifurcation diagram that is continuously connected to the initial point \((u_0, \lambda_0)\). However, it is often the case that the bifurcation diagram is not connected, with multiple branches that do not meet at bifurcation points. For example, pitchfork and transcritical bifurcations are not generic; they are destroyed under perturbation [15, Chapter IV], and subsequently the complete bifurcation diagram cannot be computed in one pass with the approach described above. Other examples will be given in section 4. In these cases, the diagram returned by switching continuation along a single path is incomplete, giving an unsatisfactory picture of the solutions to (1.1).

In this work we develop and analyze an alternative algorithm, deflated continuation, that is capable of discovering disconnected branches from known ones, without
requiring that a bifurcation point connect the two, Figure 1.2. At the heart of the method is the deflation of known solutions [7, 14]. Deflation is a technique that systematically modifies a nonlinear problem to guarantee that Newton’s method will not converge to a known root, thus enabling unknown roots to be discovered from the same initial guess. Fix $\lambda$ in (1.1) to yield the nonlinear problem

$$F(u) = 0,$$

(1.3)

where $F : U \to Y$. Suppose Newton’s method is applied to $F$ from initial guess $u_0$ to yield the solution $u^*_1$, with the Fréchet derivative $F'(u^*_1)$ nonsingular. Suppose further that we suspect that (1.3) permits solutions other than $u^*_1$, but no additional initial guesses are available. We thus construct a modified problem

$$G(u) = M(u; u^*_1)F(u),$$

(1.4)

via the application of a deflation operator $M(u; u^*_1)$ to the residual $F$. By construction, this deflated residual satisfies two properties. The first is the preservation of solutions of $F$, i.e. for $u \neq u^*_1$, $G(u) = 0$ iff $F(u) = 0$. The second is that Newton’s method applied to $G$ will not discover $u^*_1$ again, as

$$\lim \inf_{u \to u^*_1} ||G(u)|| > 0,$$

(1.5)

i.e. along any sequence converging to the known root, the deflated residual does not converge to zero. Thus, if Newton’s method applied to $G$ converges from $u_0$, it will converge to a distinct solution $u^*_2 \neq u^*_1$. The process can then be repeated until no more solutions are found from $u_0$ in a specified number of Newton iterations. In this work, we use the shifted deflation operator

$$M(u; u^*_1) = \left( \frac{1}{||u - u^*_1||^p} + \sigma \right) I,$$

(1.6)

where $I$ is the identity on $Y$, $p$ is the power, and $\sigma$ is the shift. All of the examples below use $p = 2$ and $\sigma = 1$. Importantly, it is possible to efficiently solve the Newton
step for $G$ if a good preconditioner is available for the Newton step of $F$. For more details, see [1, 14, 13].

We present the proposed bifurcation algorithm in section 2. To analyze its behaviour, in section 3 we develop an initial theory of multiconvergence of Newton’s method. We derive novel sufficient conditions under which Newton’s method will converge to two different solutions, starting from the same initial guess. In section 4, the method is applied to several problems on which switching continuation fails.

Algorithm 2.1. Deflated continuation.

Input: Initial parameter value $\lambda_{\text{min}}$.
Input: Final parameter value $\lambda_{\text{max}} > \lambda_{\text{min}}$.
Input: Step size $\Delta \lambda > 0$.
Input: Nonlinear residual $f(u, \lambda)$.
Input: Deflation operator $M(u; u^*)$.
Input: Initial solutions $S(\lambda_{\text{min}})$ to $f(\cdot, \lambda_{\text{min}})$.

1: $\lambda \leftarrow \lambda_{\text{min}}$
2: while $\lambda < \lambda_{\text{max}}$ do
3: $F(\cdot) \leftarrow f(\cdot, \lambda + \Delta \lambda)$ \Comment{Fix the value of $\lambda$ to solve for.}
4: $S(\lambda + \Delta \lambda) \leftarrow \emptyset$
5: for $u_0 \in S(\lambda)$ do \Comment{Continue known branches.}
6: apply Newton’s method to $F$ from initial guess $u_0$.
7: if solution $u^*$ found then
8: $S(\lambda + \Delta \lambda) \leftarrow S(\lambda + \Delta \lambda) \cup \{u^*\}$ \Comment{Record solution.}
9: $F(\cdot) \leftarrow M(\cdot; u^*)F(\cdot)$ \Comment{Deflate solution.}
10: for $u_0 \in S(\lambda)$ do \Comment{Seek new branches.}
11: success $\leftarrow$ true
12: while success do
13: apply Newton’s method to $F$ from initial guess $u_0$.
14: if solution $u^*$ found then \Comment{New branch found.}
15: $S(\lambda + \Delta \lambda) \leftarrow S(\lambda + \Delta \lambda) \cup \{u^*\}$ \Comment{Record solution.}
16: $F(\cdot) \leftarrow M(\cdot; u^*)F(\cdot)$ \Comment{Deflate solution.}
17: else
18: success $\leftarrow$ false
19: $\lambda \leftarrow \lambda + \Delta \lambda$
20: return $S$

2. Deflated continuation. Let $[\lambda_{\text{min}}, \lambda_{\text{max}}]$ be the interval of interest for the parameter $\lambda$, and let $\Delta \lambda$ be the continuation step size. For a given $\lambda$, let $S(\lambda) \subset U$ denote the set of known solutions to (1.3). Given $S(\lambda)$, Algorithm 2.1 constructs $S(\lambda + \Delta \lambda)$ as follows. In the first pass (lines 5–9), known solutions are continued with standard classical continuation; each known solution $u_0 \in S(\lambda)$ is used as initial guess for $f(\cdot, \lambda + \Delta \lambda)$ in turn. If some solutions are not successfully continued, the algorithm proceeds with the other branches regardless. (This can happen at fold bifurcations, for example.) As each solution is continued, it is recorded and deflated. In the second pass (lines 10–18), each initial guess is again considered in turn. Deflation guarantees that Newton’s method will not return to the known branch, and hence if Newton’s method converges, it will converge to a previously unknown solution (line 14). Each initial
guess is attempted repeatedly until no solution is found within a certain number of Newton iterations. (Recall that Newton’s method is undecidable, i.e. it is impossible to decide in general if Newton’s method will eventually converge for a given initial guess [6].) Once all initial guesses have been exhausted, the algorithm increments $\lambda$ and continues until the end of the interval has been reached.

2.1. Variants of the algorithm. Various modifications to the basic algorithm are possible. The analyst may decide to seek unknown branches with a step size larger than $\Delta \lambda$, to reduce the effort spent on unsuccessful Newton iterations. The continuation and discovery stages are independent and may be executed in parallel; one group of processors can continue known solutions forwards, while other groups follow behind, seeking new solutions to continue.

If the system (1.1) has a finite symmetry group $\mathcal{G}$ such that for all $g \in \mathcal{G}$,

$$f(u, \lambda) = 0 \iff f(gu, \lambda) = 0,$$

(2.1)

then when a solution $u$ is discovered, its actions $\mathcal{G}u$ should be recorded and deflated as well, assuming that it is possible to represent each $gu$ exactly with the discretization employed. If the discretization does not respect this symmetry (e.g. a finite element discretization on an unstructured mesh), then the projection of $gu$ should be used as initial guess for Newton’s method instead. Deflating infinite symmetry groups will be studied in future research.

If the system (1.1) has a trivial branch $\bar{u}$ such that $f(\bar{u}, \lambda) = 0$ for all $\lambda$, then this branch must be excluded from the set of initial guesses to use in deflation. This is because the initial residual of (1.4) will evaluate to $0/0$. As such trivial branches are obvious from the equations, the simplest approach is just to deflate any trivial solutions away before beginning Algorithm 2.1.

In the discovery stage, problem-specific guesses other than the previous solutions may be employed; for example, in nonlinear eigenproblems it may be useful to use the eigenmodes of an associated linear problem. It may be necessary to break the symmetry of the guesses: if the system (1.1) has a $\mathbb{Z}_2$ symmetry $R$ such that $f(Ru, \lambda) = Rf(u, \lambda)$, then if Newton’s method is initialized with a symmetric initial guess satisfying $Ru_0 = u_0$ then all subsequent iterates will also remain symmetric. This will cause nonconvergence to nonsymmetric solutions, such as those introduced at a symmetry-breaking bifurcation. In this regard it may be advantageous to deliberately break the symmetry of the discretization, or if this is not possible (such as when using a spectral method), to deliberately break the symmetry of the initial guesses.

It is straightforward in principle to employ other continuation approaches in Algorithm 2.1: if arclength continuation is used, then in the first pass each branch is synchronized at $\lambda + \Delta \lambda$, deflation is applied to seek new branches, and the process is repeated.

3. Convergence analysis. The central question in the analysis of Algorithm 2.1 is: under what circumstances will unknown branches be discovered, and under what circumstances will they be missed? Given an initial guess $u_0$, we wish to derive sufficient conditions that guarantee convergence to at least two solutions $u^*_1$ and $u^*_2$ with Newton’s method and deflation, Figure 3.1. In the context of Algorithm 2.1, $u_0$ is the known solution for $f(\cdot, \lambda)$, $u^*_1$ is the solution on the same branch for $f(\cdot, \lambda + \Delta \lambda)$, and $u^*_2$ is another solution to $f(\cdot, \lambda + \Delta \lambda)$ on a different branch.

The best-known theorem of convergence for Newton’s method is the theorem of Kantorovich [16], who first formulated and analyzed Newton’s method in Banach
Fig. 3.1: Sketch of the regions of convergence around solutions $u^*_1$ and $u^*_2$ before and after deflation. Before deflation, the initial guess $u_0$ converges to $u^*_1$; after deflating this solution, the region of convergence around $u^*_2$ expands and $u_0$ now lies within it.

There exist $u^*_1$ and $u^*_2$ with $F(u^*_1) = F(u^*_2) = 0$ and $u^*_1 \neq u^*_2$. Now consider an initial guess $u_0$ that provably converges to $u^*_1$ by the Newton–Kantorovich theorem. The result is a $\rho^+$ such that $u^*_1 \in B(u_0, \rho^+)$ and $u^*_2 \notin B(u_0, \rho^+)$. Figure 3.2a. In order to prove convergence of the deflated function $M(u; u^*_1)F(u)$, we would need to establish a $\rho'^+ > \rho^+$ such that $u^*_2 \in B(u_0, \rho'^+)$. However, this would imply that $u^*_1 \in B(u_0, \rho'^+)$. The assumptions of the Newton–Kantorovich theorem imply that the Fréchet derivative is invertible everywhere in the ball, but the Fréchet derivative of the deflated function is not defined at $u^*_1$, and hence the assumptions

---

**Theorem 3.1 (Affine-covariant Newton–Kantorovich [16])**. Let $F : D \rightarrow Y$ be a continuously Fréchet differentiable function on the open convex subset $D \subseteq U$. Given $u_0 \in D$, assume that

i) $F'(u_0)^{-1}$ exists; let $\alpha = \|F'(u_0)^{-1}F(u_0)\|;$

ii) $\|F'(u_0)^{-1}(F'(u) - F'(v))\| \leq \omega_0\|u - v\|$ for all $u, v \in D$;

iii) $h_0 = \alpha\omega_0 \leq \frac{1}{2}$;

iv) $B = \bar{B}(u_0, \rho_0) \subset D$ for $\rho_0 = (1 - \sqrt{1 - 2h_0})/\omega_0$, where $B$ defines an open ball.

Then the Newton sequence from $u_0$ is well-defined and remains within the ball $B$. A solution $u^* \in B$ with $F(u^*) = 0$ exists, and the Newton sequence converges to it. Furthermore, if we define $\rho^+ = (1 + \sqrt{1 - 2h_0})/\omega_0$, then $u^*$ is unique within $D \cap B(u_0, \rho^+)$. One of the main features of this theorem is that all of its assumptions except for Lipschitz continuity are verified at the initial guess $u_0$. Convergence can be assured a priori, without needing to assume the existence of a root beforehand.

Nevertheless, this theorem is not a suitable foundation for the purpose at hand. Suppose there exist $u^*_1$ and $u^*_2$ with $F(u^*_1) = F(u^*_2) = 0$ and $u^*_1 \neq u^*_2$. Now consider an initial guess $u_0$ that provably converges to $u^*_1$ by the Newton–Kantorovich theorem. The result is a $\rho^+$ such that $u^*_1 \in B(u_0, \rho^+)$ and $u^*_2 \notin B(u_0, \rho^+)$. Figure 3.2a. In order to prove convergence of the deflated function $M(u; u^*_1)F(u)$, we would need to establish a $\rho'^+ > \rho^+$ such that $u^*_2 \in B(u_0, \rho'^+)$. However, this would imply that $u^*_1 \in B(u_0, \rho'^+)$. The assumptions of the Newton–Kantorovich theorem imply that the Fréchet derivative is invertible everywhere in the ball, but the Fréchet derivative of the deflated function is not defined at $u^*_1$, and hence the assumptions

---

Spaces. We state the theorem (and all subsequent results) in affine-covariant form [9].
cannot hold after deflation. The same argument holds for the Newton–Mysovskikh theorem [22].

We therefore seek to base our analysis on results whose conditions are verified at the roots themselves, instead of at the initial guess. The theorem we will build upon is the Rall–Rheinboldt theorem [24, 26], again stated in affine-covariant form.

**Theorem 3.2** (Affine-covariant Rall-Rheinboldt [24, 26]). Let \( F : D \rightarrow Y \) be a continuously Fréchet differentiable function on the open convex subset \( D \subseteq U \). Suppose that there exists a \( u^* \in D \) such that \( F(u^*) = 0 \), and suppose further that

1. \( F'(u^*)^{-1} \) exists;
2. \( \|F'(u^*)^{-1}(F'(u) - F'(v))\| \leq \omega^* \|u - v\| \) for all \( u, v \in D \).

Then any \( \rho^* \leq 2/(3\omega^*) \) such that \( B = B(u^*, \rho^*) \subset D \) has the property that starting at \( u_0 \in B \), the Newton sequence is well-defined and remains within \( B \). The Newton sequence converges to \( u^* \in B \). Furthermore, if we define \( \rho^+ = 1/\omega^* \), then \( u^* \) is unique within \( D \cap B(u^*, \rho^+) \).

A crucial ingredient of this theorem is the affine covariant Lipschitz continuity of the Fréchet derivative \( F' \). Before extending this theorem to the deflated case, we first give a lemma regarding the product of Lipschitz continuous functions.

**Lemma 3.3** (Product of Lipschitz continuous functions). Let \( X, Y \) and \( Z \) be Banach spaces and let \( L(Y, Z) \) be the vector space of bounded linear operators from \( Y \) to \( Z \) with induced operator norm. Let \( F : X \rightarrow Y \) and \( G : X \rightarrow L(Y, Z) \) be Lipschitz continuous functions on the open subset \( D \subseteq X \) with Lipschitz constants \( \omega_F \) and \( \omega_G \) respectively. Assume further that \( F \) and \( G \) are bounded on \( D \), i.e. there exist \( N_F, N_G \in \mathbb{R} \) such that \( \|F(x)\| < N_F \) and \( \|G(x)\| < N_G \) for all \( x \in D \). Then the product \( GF : X \rightarrow Z \) is bounded and Lipschitz continuous on \( D \) with Lipschitz
constant \((N_F\omega_G + N_G\omega_F)\).

**Proof.** Let \(x, y \in D\). As both \(F\) and \(G\) are bounded on \(D\) their product is bounded as well:

\[
\|G(x)F(x)\| \leq \|G(x)\|\|F(x)\| \leq N_GN_F < \infty. \quad (3.1)
\]

Furthermore,

\[
\|G(x)F(x) - G(y)F(y)\| = \|G(x)F(x) - G(x)F(y) + G(x)F(y) - G(y)F(y)\|
\]

\[
\leq \|G(x)F(x) - G(x)F(y)\| + \|G(x)F(y) - G(y)F(y)\|
\]

\[
\leq \|G(x)\|\|F(x) - F(y)\| + \|G(x) - G(y)\|\|F(y)\|
\]

\[
\leq N_G\|F(x) - F(y)\| + N_F\|G(x) - G(y)\|
\]

\[
\leq N_G\omega_F\|x - y\| + N_F\omega_G\|x - y\|
\]

\[
= (N_F\omega_G + N_G\omega_F)\|x - y\|, \quad (3.2)
\]

which proves the claim. \(\square\)

We now consider the situation where one solution \(u_1^*\) is known and has been deflated. We state sufficient conditions on the original residual and deflation operator that guarantee convergence to another solution \(u_2^*\).

**Theorem 3.4.** Let \(F : D \to Y\) be a continuously Fréchet differentiable function on the open convex subset \(D \subseteq U\). Suppose there exists \(u_2^* \in D\) such that \(F(u_2^*) = 0\). Further assume there exists \(u_1^* \in D\), \(u_1^* \neq u_2^*\), such that \(F(u_1^*) = 0\). This solution is deflated with a deflation operator \(M(\cdot; u_1^*) : D \setminus \{u_1^*\} \to \mathcal{GL}(Y, Y)\). Suppose there exists an open bounded convex subset \(E \subseteq D \setminus \{u_1^*\}\) with \(u_2^* \in E\) such that the following conditions hold:

i) \(F'(u_2^*)^{-1}\) exists;

ii) \(\|F'(u_2^*)^{-1}(F'(u) - F'(v))\| \leq \omega^*\|u - v\|\) for all \(u, v \in E\);

iii) \(M(u; u_1^*)\) is continuously Fréchet differentiable for all \(u \in E\);

iv) \(\|M'(u; u_1^*) - M'(v; u_1^*)\| \leq \omega_{M'}\|u - v\|\) for all \(u, v \in E\).

Then there exists a \(\rho > 0\) such that the Newton sequence from \(u_0 \in B = B(u_2^*, \rho)\) on the deflated function \(M(u; u_1^*)F(u)\) is well-defined, remains in \(B\) and converges to \(u_2^* \in B\).

If the norm on \(U\) is twice continuously differentiable on \(E\), the deflation operator (1.6) satisfies these conditions. In this case, we can use the composition rule for differentiable functions to show that the deflation operator is in turn twice differentiable on \(E\). This implies that the deflation operator is Lipschitz continuous, as \(E\) is bounded. For \(2 \leq p < \infty\), the \(L^p\) norm is at least twice continuously differentiable on any open subset not containing zero [28, Theorem 8]. More generally, if the Banach space \(U\) is isomorphic to a Hilbert space, then it can be equipped with twice differentiable norms [18, 11]. Thus, the conditions demanded are satisfied in typical cases of interest.

**Proof.** As \(F(u)\) and \(M(u; u_1^*)\) are continuously Fréchet differentiable on \(E\), they are Lipschitz continuous as well by boundedness of \(E\). Lipschitz continuity implies that the operators are bounded on \(E\) and thus \(F(u), F'(u), M(u; u_1^*)\) and \(M'(u; u_1^*)\) are all bounded on \(E\). As a result the Fréchet derivative of the deflated operator

\[
(M(u; u_1^*)F(u))' = M(u; u_1^*)F'(u) + M'(u; u_1^*)F(u) \quad (3.3)
\]
is Lipschitz continuous by use of the triangle inequality and Lemma 3.3.

Since \( u^*_2 \) is a root of \( F \), the Fréchet derivative of the deflated residual is
\[
M(u^*_2; u^*_1)F'(u^*_2).
\]
For any \( u \in D \) the deflation operator \( M(u; u^*_1) \in GL(Y, Y) \) and is thus invertible. The Fréchet derivative of the deflated residual is thus invertible at \( u^*_2 \) with
\[
\left( \frac{M(u; u^*_1)F(u)}{u^*_2} \right)^{-1} = \frac{F'(u^*_2)}{u^*_2} \frac{M(u^*_2; u^*_1)^{-1}}{.}
\]

Combining these facts, there exists an (affine covariant) \( \tilde{\omega}_2 > 0 \) such that
\[
\left\| \left( \frac{M(u^*_2; u^*_1)F(u^*_2)}{u^*_2} \right)^{-1} \left( M(u; u^*_1)F(u) \right)' - (M(u; u^*_1)F(v))' \right\| \leq \tilde{\omega}_2 \left\| u - v \right\|,
\]
for all \( u, v \in E \). Hence the conditions of Theorem 3.2 are satisfied for both \( F(u) \) and \( M(u; u^*_1)F(u) \), and it can be applied to prove the claim.

We are now in a position to state sufficient conditions for convergence to two solutions with deflation and Newton’s method. The proof applies the previous theorem, Theorem 3.4, and the Rall–Rheinboldt theorem, Theorem 3.2.

**Theorem 3.5** (Deflated Rall-Rheinboldt [4]). Let \( F : D \rightarrow Y \) be a continuously Fréchet differentiable function on an open subset \( D \subseteq U \). Suppose there exist \( u^*_1, u^*_2 \in D \) such that \( F(u^*_1) = F(u^*_2) = 0 \), \( u^*_1 \neq u^*_2 \). Let \( E_1 \) be an open bounded convex subset such that \( E_1 \subset D \backslash \{ u^*_2 \} \) and \( u^*_1 \in E_1 \). Furthermore let \( E_2 \) be an open bounded convex subset such that \( E_2 \subset D \backslash \{ u^*_1 \} \) and \( u^*_2 \in E_2 \). Let \( M(\cdot; u^*_1) : D \backslash \{ u^*_1 \} \rightarrow GL(Y, Y) \) be a deflation operator such that the following conditions hold:

i) \( F'(u^*_1)^{-1} \) and \( F'(u^*_2)^{-1} \) exist;

ii) \( \|F'(u^*_1)^{-1}(F'(u) - F'(v))\| \leq \omega_1^* \|u - v\| \) for all \( u, v \in E_1 \);

iii) \( \|F'(u^*_2)^{-1}(F'(u) - F'(v))\| \leq \omega_2^* \|u - v\| \) for all \( u, v \in E_2 \);

iv) \( M(u; u^*_1) \) is continuously Fréchet differentiable for all \( u \in E_2 \);

v) \( \|M'(u; u^*_1) - M'(v; u^*_1)\| \leq \omega_M \|u - v\| \) for all \( x, y \in E_2 \).

Then there exists an \( \tilde{\omega}_2 > 0 \) such that for all \( u, v \in E_2 \) there holds
\[
\left\| \left( \frac{M(u^*_2; u^*_1)F(u^*_2)}{u^*_2} \right)^{-1} \left( M(u; u^*_1)F(u) \right)' - (M(u; u^*_1)F(v))' \right\| \leq \tilde{\omega}_2 \left\| u - v \right\|.
\]

If \( \|u^*_1 - u^*_2\| < \rho_1 + \rho_2 \) for some \( \rho_1 \leq 2/(3\omega_1^*) \) and \( \rho_2 \leq 2/(3\omega_2^*) \) such that we have \( B_1 = B(u^*_1, \rho_1) \subset E_1 \) and \( B_2 = B(u^*_2, \rho_2) \subset E_2 \), then the intersection \( B_1 \cap B_2 \) is nonempty. Starting from any \( u_0 \in B_1 \cap B_2 \), Newton’s method will first converge to \( u^*_1 \in E_1 \) and then after deflation with \( M(\cdot; u^*_1) \) will converge to \( u^*_2 \in E_2 \).

The argument of Theorems 3.4 and 3.5 can be applied again to derive sufficient conditions for a single initial guess to converge to three or more solutions.

A natural question to ask is if Algorithm 2.1 will recover the behaviour of switching continuation, i.e. if it will always discover connected branches for sufficiently small \( \Delta \lambda \). This is discussed in the following corollary.

**Corollary 3.6** (Connected roots). Let \( f : D \times \mathbb{R} \rightarrow Y \) and suppose there exists a \( \lambda_c \in \mathbb{R} \) such that \( f(\cdot, \lambda) : D \rightarrow Y \) is a continuously Fréchet differentiable
function on the open subset $D \subseteq U$ for $\lambda > \lambda_c$. Furthermore assume that there exists $u_1^*(\lambda), u_2^*(\lambda) \in D$ such that $f(u_1^*(\lambda), \lambda) = f(u_2^*(\lambda), \lambda) = 0$ and $u_1^*(\lambda) \neq u_2^*(\lambda)$ for $\lambda > \lambda_c$ and $u_1^*(\lambda_c) = u_2^*(\lambda_c)$. Assume that for fixed $\lambda > \lambda_c$ all conditions from Theorem 3.5 hold for the function $f(\cdot, \lambda) : D \to Y$ so that $\rho_1(\lambda), \rho_2(\lambda) \in \mathbb{R}$ as in Theorem 3.5 are well defined. If

$$\lim_{\lambda \downarrow \lambda_c} \frac{\|u_1^*(\lambda) - u_2^*(\lambda)\|}{\rho_1(\lambda) + \rho_2(\lambda)} < 1, \quad (3.7)$$

then an initial guess $u_0 \in D$ exists which converges to both $u_1^*$ and $u_2^*$ using Newton’s method and deflation for $\lambda$ sufficiently close to $\lambda_c$.

By assumption, $\|u_1^*(\lambda) - u_2^*(\lambda)\| \to 0$ as $\lambda \downarrow \lambda_c$. As $\rho_1(\lambda) < \|u_1^*(\lambda) - u_2^*(\lambda)\|$ (and similarly for $\rho_2(\lambda)$), $\rho_1(\lambda) + \rho_2(\lambda) \to 0$ also. Thus, the evaluation of the left-hand side of (3.7) requires the application of L’Hôpital’s rule.

A similar formulation applies to the case of branches meeting as $\lambda \uparrow \lambda_c$, and to more than two roots. Our practical experience does indeed suggest that Algorithm 2.1 is always able to find branches connected via a bifurcation point; we conjecture that (3.7) always holds for sufficiently regular functions.

Note that these results are nonconstructive, i.e. the Lipschitz constants arising and the resulting radii of convergence are not in general known. Thus, it could be the case that the region of multiconvergence is too small to be of practical use in bifurcation analysis. We therefore apply Algorithm 2.1 to several problems of interest in the literature to investigate the robustness and efficiency of deflated continuation.

4. Examples.

4.1. Roots of unity. We consider the complex roots of unity

$$z^q - 1 = 0 \quad (4.1)$$

as the exponent $q$ is varied. For $q \in \mathbb{N}_+$, the solutions are $\exp(2\pi ik/q)$ for $k = 1, \ldots, q$; this example studies how these solutions bifurcate for non-integer exponents.

Algorithm 2.1 was applied to (4.1) from $q = 2$ to $q = 9$ with $\Delta q = 0.1$. Deflation was applied with power $p = 2$ and shift $\sigma = 1$. The resulting bifurcation diagram is shown in Figure 4.1, where the quantity plotted is the argument of the solution. For $q = 2$, the solutions are $z = \pm 1$: the solution $z = -1$ bifurcates and the resulting solutions approach $z = \pm i$ as $q \to 4$. At $q = 4$, $z = -1$ undergoes another bifurcation, and the process repeats. In general there is a bifurcation at $z = -1$ for $q \in 2\mathbb{N}_+$, and the resulting branches are mutually disconnected from each other.

As the bifurcation diagram is disconnected, switching continuation would identify at most one branch from any given initial solution. By contrast, deflated continuation identifies the new solutions at $z = -1$ immediately and correctly computes the entire diagram.

4.2. Deformation of a slender beam. The deformation of a slender vertical beam under loading is governed by Euler’s elastica equation [19]

$$\theta'' + \lambda^2 \sin(\theta) = \mu, \quad \theta(0) = \theta(1) = 0, \quad (4.2)$$

where $s$ is the arclength along the beam, $\theta(s)$ is the angle relative to the vertical axis, $\lambda$ is the longitudinal force and $\mu$ is the transversal force. This system has long served as a model problem in bifurcation analysis [25].
Algorithm 2.1 was applied to (4.2), from $\lambda = 0$ to $\lambda = 4\pi$, with continuation step $\Delta \lambda = 0.1$. The equation was discretized with $10^4$ piecewise linear finite elements using FEniCS [20] and PETSc [3]. In the absence of a transversal force ($\mu = 0$), the initially straight solution $\theta(s) = 0$ forms a trivial branch and was thus deflated before beginning Algorithm 2.1. Newton’s method was terminated with failure if convergence did not occur within $10^2$ iterations. Deflation was applied with power $p = 2$, shift $\sigma = 1$ and with distances measured in the $H^1$ norm. After the forward continuation pass, arclength continuation backwards in $\lambda$ was performed (without deflation) to complete the small sections of the bifurcation diagram where branches were not immediately discovered (cf. Figure 1.2b). The functional used was the $L^2$ norm, signed by $\text{sign}(\theta'(0))$.

A series of pitchfork bifurcations at $\lambda = n\pi$ for $n \in \mathbb{N}_+$ (corresponding to the eigenvalues of the associated linear problem) result in the buckled modes emanating from the trivial branch. As all branches meet at bifurcation points with the trivial branch, both switching continuation and deflated continuation compute the entire bifurcation diagram, Figure 4.2a. However, if a transversal force is applied ($\mu = 1/2$), the reflective symmetry is destroyed and the symmetric pitchfork bifurcations degenerate. In this case, the initial branch disconnects from all other branches, resulting
Fig. 4.2: Bifurcation diagrams for the Euler elastica equation (4.2) as a function of longitudinal loading $\lambda$, for $\mu = 0$ and $\mu = 1/2$. For $\mu = 0$, the bifurcation diagram is continuous and both switching continuation and deflated continuation discover the entire diagram. For $\mu = 1/2$, the bifurcation diagram is disconnected: switching continuation only discovers the part of the diagram labelled with red circles, whereas deflated continuation correctly computes the entire diagram. Blue squares denote the discovery of disconnected branches with deflation.

in a disconnected bifurcation diagram, Figure 4.2b. All of these other branches are missed with switching continuation applied to this path, yielding an incomplete representation of the dynamics of the system\(^1\). Deflated continuation correctly computes the bifurcation diagram without continuation along multiple parameters.

4.3. Nonlinear pendulum. In the previous example, an additional source term destroyed the symmetry of the bifurcation diagram. This example serves to demonstrate that the same effect can be achieved by inhomogeneous boundary conditions. The angle of a pendulum to the vertical is described by the same equation,

$$\theta'' + \sin \theta = 0,$$

but here we impose inhomogeneous Dirichlet conditions $\theta(0) = \theta(10) = 2$. It is well known that with these boundary conditions this equation permits multiple solutions [5]. One possible way to compute these solutions is to attempt a homotopy from the linear equation $\theta'' = 0$ via the addition of a parameter $\varepsilon$ multiplying the nonlinear term:

$$\theta'' + \varepsilon \sin \theta = 0, \quad \theta(0) = \theta(10) = 2.$$  \hspace{1cm} (4.4)

For $\varepsilon = 0$, (4.4) reduces to a trivial linear problem; for $\varepsilon = 1$, the problem of interest is recovered. It is clear that homotopy methods based on switching continuation will

\(^1\)It is possible to identify all of these solutions with switching continuation as follows: set $\mu = 0$ and continue $\lambda$ from 0 to $4\pi$; set $\lambda = 4\pi$ and continue $\mu$ from 0 to $1/2$; set $\mu = 1/2$ and continue $\lambda$ from $4\pi$ to 0. However, this is laborious and requires expert knowledge of the system; the right continuation strategy may not be obvious in more complex cases.
identify a solution for $\varepsilon = 1$ only if there is a branch that continuously connects it to the solution for $\varepsilon = 0$ [23, §11.3].

Algorithm 2.1 was applied to (4.4), from $\varepsilon = 0$ to $\varepsilon = 1$, with continuation step $\Delta \varepsilon = 10^{-2}$. The equation was discretized with $10^4$ standard piecewise linear finite elements using FEniCS and PETSc. The same deflation and solver settings were used as in the previous example. The functional considered was the product of the derivative at the left endpoint and the $H^1$ norm of the solution.

The resulting bifurcation diagram is shown in Figure 4.3. For $\varepsilon = 0$, the problem has a unique solution; as continuation is applied to this branch, no bifurcation points are encountered, and hence with switching continuation only one solution would be identified for $\varepsilon = 1$. As previously mentioned, a major difficulty with such homotopy methods is that the resulting bifurcation diagram must continuously connect the solution for $\varepsilon = 0$ to those of $\varepsilon = 1$: homotopy works robustly if this property holds, and fails if it does not. With deflated continuation, the requirements for success are weakened. Given a branch $\{(u(t), \lambda(t)) : t \in [0, 1]\}$, define its support to be

---

2Another approach would be to consider the associated initial-value problem with boundary conditions $\theta(0) = 2, \theta'(0) = \varepsilon$. The resulting IVP can be solved for varying values of $\varepsilon$ and the solutions with $\theta(10) = 2$ selected. This shooting approach does not generalize to higher dimensions, and can be unstable.
$\{\lambda(t) : t \in [0, 1]\} \subset \mathbb{R}$. Whereas switching continuation homotopy finds a solution only if there exists a continuously connected branch between it and the initial guess, deflated continuation homotopy only necessitates that the union of the supports of the branches covers the interval $[\lambda_{\text{min}}, \lambda_{\text{max}}]$. This is precisely the case in Figure 4.3. As the supports of the branches intersect, Algorithm 2.1 is able to discover the disconnected branches that come into existence at $\varepsilon \approx 0.575$ and $\varepsilon \approx 0.697$, and identifies four additional solutions that switching continuation homotopy neglects along this path.

4.4. Deformation of a hyperelastic beam. A major strength of deflated continuation is that it scales to fine discretizations of partial differential equations (PDEs). Unlike switching continuation, deflated continuation does not demand the non-scalable computation of determinants or difficult eigendecompositions to detect bifurcations or switch branches. In fact, all of the subproblems arising in deflated continuation can be solved efficiently if a good preconditioner is available for the underlying forward problem.

The example of section 4.2 modelled the deformation of a beam under compression with Euler’s elastica equation. In this example, we model the same physical phenomenon, but with a two-dimensional compressible neo-Hookean hyperelastic PDE, solved with scalable Krylov methods and preconditioners. The potential energy $\Pi$ is given by

$$\Pi(u) = \int_{\Omega} \psi(u) \, dx - \int_{\Omega} B \cdot u \, dx - \int_{\partial\Omega} T \cdot u \, ds,$$

(4.5)

where $\Omega$ is the reference domain, $u : \Omega \to \mathbb{R}^2$ is the displacement, $\psi$ is the elastic stored energy density, $B$ is the body force per unit reference area, and $T$ is the traction force per unit reference length. To define $\psi$, consider the deformation gradient

$$F = I + \nabla u,$$

(4.6)

the right Cauchy-Green tensor

$$C = F^T F,$$

(4.7)

and its invariants $J = \det(C)$ and $I_c = \text{tr}(C)$. The compressible neo-Hookean stored energy density is given by

$$\psi = \frac{\mu}{2} (I_c - 2) - \mu \log(J) + \frac{\lambda}{2} \log(J)^2,$$

(4.8)

where $\mu$ and $\lambda$ are the Lamé parameters, which are calculated from the Young’s modulus $E$ and Poisson ratio $\nu$. In this problem, we take $\Omega = (0, 1) \times (0, 0.1)$, $B = (0, -1000)$, $T = 0$, $E = 10^6$, and $\nu = 0.3$. In addition, Dirichlet conditions are imposed on the left and right boundaries:

$$u(0, \cdot) = (0, 0),$$

(4.9)

$$u(1, \cdot) = (0, -\varepsilon),$$

(4.10)

where $\varepsilon$ is the parameter to be continued.

For a fixed $\varepsilon$, let $V_\varepsilon = \{u \in H^1(\Omega; \mathbb{R}^2) : u(0, \cdot) = (0, 0), u(1, \cdot) = (0, -\varepsilon)\}$ be the function space of admissible displacements. Minimizers of (4.5) are computed by seeking solutions of the associated optimality condition: find $u \in V_\varepsilon$ such that

$$\Pi'(u; v) = 0 \forall v \in V_0.$$
Buckling of a hyperelastic beam

Fig. 4.4: Bifurcation diagram for the hyperelastic PDE formulation for the deformation of a beam (4.11) as a function of the displacement on the right-hand boundary. As before, switching continuation only discovers that part of the diagram labelled with red circles. Blue squares denote the discovery of disconnected branches with deflation.

Algorithm 2.1 was applied to (4.11), from $\varepsilon = 0$ to $\varepsilon = 0.2$, with continuation step $\Delta \varepsilon = 0.0005$. The equation was discretized with $2 \times 10^4$ piecewise linear finite elements using FEniCS and PETSc. Newton’s method was terminated with failure if convergence did not occur within $10^2$ iterations. Each Newton step was solved with the GAMG algebraic multigrid preconditioner [2], equipped with the near-nullspace of rigid body modes [12]. Deflation was applied with power $p = 2$, shift $\sigma = 1$ and with distances measured in the $H^1$ norm. The functional considered was the vertical component of displacement evaluated at $(0.25, 0.05)$.

It is well-known that for $B = T = 0$, (4.11) enjoys a $\mathbb{Z}_2$ reflective symmetry and its bifurcation diagram undergoes a series of pitchfork bifurcations as $\varepsilon$ is increased, similar to Figure 4.2a. However, in this configuration the reflective symmetry has been broken by imposing a gravitational body force, causing the bifurcation diagram to disconnect. The resulting diagram is shown in Figure 4.4, and the computed solutions with positive functional value are shown in Figure 4.5. The bifurcation diagram has been computed correctly, indicating that Algorithm 2.1 is robust to the use of indirect solvers, and that it will scale to much finer discretizations of PDEs.

4.5. A generalized Bratu–Gelfand problem in two dimensions. Previous examples have demonstrated that deflated continuation is able to find branches that
switching continuation misses because they are disconnected. Switching continuation can fail in other ways: for example, if a bifurcation is caused by an eigenvalue of even multiplicity crossing the origin, the standard bifurcation test functional (1.2) will neglect it. This example exhibits such a bifurcation, and demonstrates that deflated continuation is robust to this failure mode.

We consider the problem of Mittelmann [21]:

$$-
abla^2 y = -10(y - \lambda e^y) \equiv \phi(y, \lambda), \quad \text{in } \Omega = (-0.5, 0.5)^2,$$
$$\nabla y \cdot \hat{n} = 0, \quad \text{on } \partial\Omega. \quad (4.12)$$

This is a generalization of the Bratu–Gelfand problem to multiple dimensions with the addition of a linear term, and has been used as a test problem for the PLTMG [21] and pde2path [29] continuation codes.

As noted by Mittelmann, this equation has two spatially constant solutions that satisfy \( \phi(y, \lambda) = 0 \), i.e. \( y(x) = \bar{y} \) with \( \bar{y} = \lambda e^{\bar{y}} \). Linearising around \( \bar{y} \) with \( y = \bar{y} + w \) yields an eigenvalue problem

$$-\nabla^2 w = \left. \frac{\partial \phi}{\partial y} \right|_{(\bar{y}, \lambda)} \equiv w = -10(1 - \bar{y})w, \quad \text{in } \Omega, \quad (4.13)$$
$$\nabla w \cdot \hat{n} = 0, \quad \text{on } \partial\Omega.$$
Fig. 4.6: Bifurcation diagram for the Mittelmann problem in two dimensions (4.12) as a function of $\lambda$. Standard switching continuation approaches that rely on the sign of the determinant (1.2) as a bifurcation test functional only discover that part of the diagram labelled with red circles. Blue squares denote the branch overlooked by switching continuation, but found by deflated continuation. Compare with [21, Figure 1], [29, Figure 2a].

Non-trivial perturbations of the constant solutions can be located by examining the eigenvalues and corresponding eigenfunctions of the Laplacian on $\Omega$. The bifurcation points are found by solving $-10(1 - \bar{y}) = \mu_{m,n}$ where $\mu_{m,n}$ are the eigenvalues of the Laplacian with Neumann boundary conditions. In this case, $\mu_{m,n} = (m^2 + n^2)\pi^2$ for $m, n \in \mathbb{N}_+$, and thus the bifurcations occur when $\bar{y}_{m,n} = 1 + \mu_{m,n}/10$ and $\lambda_{m,n} = \bar{y}_{m,n}e^{-\bar{y}_{m,n}}$. The initial bifurcation points occur at $\lambda_{0,0} = e^{-1} \approx 0.3678$ (a fold bifurcation), $\lambda_{0,1} = \lambda_{1,0} \approx 0.2724$ (a double pitchfork bifurcation), and $\lambda_{1,1} \approx 0.1519$ (a simple pitchfork bifurcation).

Consider again the computation of the bifurcation test functional $\tau$, defined in (1.2). In the case when a simple bifurcation point is crossed $\tau$ will indicate this by negation, as one of the eigenvalues will have passed through the origin. On the other hand, if an eigenvalue of even multiplicity passes through the origin, $\tau$ remains unchanged. In this case the bifurcation point is overlooked, and the machinery of switching continuation is not activated.\footnote{Switching continuation can be rescued by deliberately breaking the symmetry of the domain, to unfold the double eigenvalues. Uecker et al. [29, Figure 4] suggest breaking the rotational symmetry of the domain by solving on $\Omega = (-0.5, 0.5) \times (-0.495, 0.495)$. The solutions found can then be continued}
As the Mittelmann problem is two-dimensional, the Laplacian has degenerate eigenvalues of even multiplicity. For example, its eigenvalues \( \mu_{0,1} \) and \( \mu_{1,0} \) are identical but correspond to different eigenfunctions (related by rotation). Thus, the associated bifurcation point at \( \lambda \approx 0.2724 \) is missed by switching continuation, even though the bifurcation diagram is connected. This deficiency is not specific to this equation, and will manifest in any situation where such degeneracy of eigenvalues occurs.

By contrast, the specific nature of the bifurcation is irrelevant to deflated continuation; we expect the algorithm to find nearby solutions regardless of the details of how the branches are connected (or not connected). To investigate this, Algorithm 2.1 was applied to (4.12), for \( \lambda \in [0.3678, 0.05] \), with continuation step \( \Delta \lambda = -0.0001 \). The equation was discretized with 1600 piecewise linear finite elements using FEniCS and PETSc. Newton’s method was terminated with failure if convergence did not occur within \( 10^2 \) iterations. The same deflation and solver settings were used as in all previous examples. Following Uecker et al. [29], the functional considered was the \( L^2 \) norm of the solution.

The resulting diagram is shown in Figure 4.6. The outer branches (on the top and bottom) are the constant solutions, with branches bifurcating from the upper branch at \( \lambda_{0,1} = \lambda_{1,0} \) as expected, and secondary bifurcations in turn emanating from these. Importantly, all branches in this interval have been discovered, including the branch overlooked with switching continuation (denoted with blue squares). Deflated continuation applies to both connected and disconnected bifurcation diagrams on which switching continuation fails.

5. Conclusion. We have presented a new algorithm for bifurcation analysis that relies on the elimination of known branches, rather than the detection and analysis of bifurcation points. In this way, the algorithm applies equally to connected and disconnected diagrams. We have developed an initial analysis of multiconvergence of Newton’s method, giving sufficient conditions for when convergence to two solutions is guaranteed. In numerical experiments the algorithm is effective and succeeds where switching continuation fails.

Unlike switching continuation, the algorithm relies only on the solution of the original nonlinear problem with a fixed parameter value, and the solution of deflations of that problem. The latter is straightforward to implement and solve if a preconditioner for the former is available. There is no need to implement augmented systems for different kinds of bifurcation points, or to compute expensive test functionals, or to construct the nullspace of singular operators. Thus, if a scalable preconditioner for the undeflated Jacobian is available, it will be possible to apply the algorithm to massive discretizations of PDEs on supercomputers.
