(Dated: October 20, 2021)

Electronic reconstruction and charge transfer in strained Sr$_2$CoIrO$_6$ double perovskite

The electronic, magnetic and optical properties of the double perovskite Sr$_2$CoIrO$_6$ (SCIO) under biaxial strain are explored in the framework of density functional theory (DFT) including a Hubbard $U$ term and spin-orbit coupling (SOC) in combination with absorption spectroscopy measurements on epitaxial thin films. While the end member SrIrO$_3$ is a semimetal with a quenched spin and orbital momentum and bulk SrCoO$_3$ is a ferromagnetic (FM) metal with spin and orbital moment of 2.50 and 0.13 $\mu_B$, respectively, the double perovskite SCIO emerges as an antiferromagnetic Mott insulator with antiparallel alignment of Co, Ir planes along the [110]-direction. Co exhibits a spin and enhanced orbital moment of $\sim 2.35 - 2.45$ and 0.31–0.45 $\mu_B$, respectively. Most remarkably, Ir acquires a significant spin and orbital moment of 1.21–1.25 and 0.13 $\mu_B$, respectively. Analysis of the orbital occupation indicates an electronic reconstruction due to a substantial charge transfer from minority to majority spin states in Ir and from Ir to Co, signaling an Ir$^{4+}$, Co$^{3+}$-configuration. Biaxial strain, varied from -1.02% ($a_{SrIrO_3}$) through 0% ($a_{SrTiO_3}$) to 1.53% ($a_{CoIrO_3}$), influences in particular the orbital polarization of the $t_{2g}$ states and leads to a nonmonotonic change of the band gap between 163 and 235 meV. The absorption coefficient reveals a two plateau feature due to transitions from the valence to the lower lying narrow $g$ bands. Inclusion of many body effects, in particular, excitonic effects by solving the Bethe-Salpeter equation (BSE), increases the band gap by $\sim$ 0.2 and improves the agreement with the measured spectrum concerning the position of the second peak at $\sim$ 2.6 eV.

Ⅰ. INTRODUCTION

The interplay of charge, spin, lattice and orbital degrees of freedom in transition metal oxides (TMO) [1] gives rise to a rich functionality. The double perovskites $A_2BB′O_6$ are a special class of TMO that allow to combine elements with different characteristics at the B and the $B′$ sites and thus achieve novel behavior [2], that can vary between ferromagnetic halfmetallic with high $T_C$ as e.g. in Sr$_2$FeMoO$_6$ to ferromagnetic insulating as in La$_2$CoMnO$_6$ [3] and Ba$_2$CuOsO$_6$ [4]. A variety of Ir-based double perovskites have been considered recently owing to their interesting electronic and magnetic properties, resulting from the interplay of spin-orbit coupling (SOC), electronic correlation and structural distortions: For example, La$_2$MgIrO$_6$ and La$_2$ZnIrO$_6$ are reported as spin-orbit magnetic Mott insulators [5]. Selecting 3d and 5d transition metal ions allows to combine the enhanced electronic correlations of the former with the strong SOC of the latter. Sr$_2$CoIrO$_6$ (SCIO) is an interesting example in this context.

The perovskite end member SrCoO$_3$ (SCO) shows ferromagnetic (FM) behavior at temperatures below $T_C$ = 280–305 K [5]. Recent DFT+$U$ studies suggested that the tetragonal $P4/mnm$ phase with moderate Jahn-Teller distortions is preferred over the $Pbnm$ phase [7]. Both experiments and theoretical calculations reveal intermediate spin (IS) state with a magnetic moment of $\sim 2.6 \mu_B$ [6,8,9]. Epitaxial strain is predicted to drive a transition from a ferromagnetic-metallic (FM-M) to an antiferromagnetic (AFM) insulating and ferroelectric phase [10].

In the other end member, SrIrO$_3$ (SIO), strong SOC leads to a splitting of the Ir-$t_{2g}$ orbitals into completely filled $j_{eff} = 3/2$ band and half-filled $j_{eff} = 1/2$. While SIO exhibits a quenched spin and orbital magnetic moment and topological crystalline semimetallic character [11,15] in space group $Pbnm$ [16], in other iridates such as the Ruddlesden-Popper (RP) Sr$_2$IrO$_4$ with Ir$^{4+}$ (5$d^5$) the interplay of electronic correlations and SOC opens a gap giving rise to a $j_{eff} = 1/2$ Mott insulator [17] [17,22].

Previous reports on the bulk double perovskite SCIO [23,26] suggested an Ir$^{5+}$, Co$^{3+}$ configuration, though there is a controversy on the magnetic state of Ir [24,26]. While the former study reports a nearly quenched Ir total magnetic moment of 0.039 $\mu_B$, the latter proposes the presence of a small fraction ($\sim 10 \%$) of Ir$^{6+}$ ($s = 3/2$) to explain a finite Ir magnetic moment. Recently, thin films of SCIO were grown on different substrates using metalorganic aerosol deposition (MAD) [25]. Polarization-dependent x-ray absorption (XAS) measurements point towards strain dependent changes in the orbital configuration and magnetocrystalline anisotropy. This goes hand in hand with a sign change of the magnetoresistance at low temperatures that could be explained by a quantitative model including anisotropic magnetoresistance and weak antilocalization effects.
Motivated by these results, we report here a comprehensive DFT+$U$ investigation including spin-orbit effects of the structural, electronic and magnetic properties of the double perovskite (DP) SCIO as a function of strain in comparison to the end members SCO and SIO. Our results confirm the semimetallic ground state of SrIrO$_3$. SrCoO$_3$ has a ferromagnetic metallic ground state in close proximity to an AFM insulating state, whereas SCIO emerges as an AFM insulator. The relaxed structures of SCO, SIO and SCIO, shown in Fig. 1 exhibit substantial octahedral rotations and tilts. In contrast to the Co$^{4+}$ and Ir$^{4+}$ electron configuration in the end members SCO and SIO, detailed analysis indicates a noticeable charge transfer from Ir to Co resulting in Co$^{4+}$ and Ir$^{3+}$ in the intermediate-spin state (IS) and an Ir$^{4+}$ configuration in the double perovskite SCIO, reminiscent of the charge transfer recently reported in SrMnO$_3$/SrIrO$_3$(001) superlattices. We note that the DP itself can be regarded as a superlattice containing alternating SrCoO$_3$ and SrIrO$_3$ layers in the (111)-direction. Furthermore, we explored the role of biaxial strain, by varying the lateral lattice constant from the one of NdGaO$_3$ (compressive), through SrTiO$_3$ (unstrained) to GdScO$_3$ (tensile). A subtle strain effect is observed in the orbital occupation and the band gap. Moreover, we have calculated the optical properties within the independent-particle (I.P.) picture, as well as by considering quasiparticle effects within the GW approximation (single shot $G_0W_0$) and excitonic effects by solving the Bethe-Salpeter equation (BSE). Changes of the in- and out-of-plane component of the real and imaginary part of the dielectric constant as a function of the lateral lattice parameter reflect the effect of strain. The calculated absorption coefficients are compared with transmission measurements on SCIO samples grown on different substrates using the MAD technique.

The paper is structured as follows: In Section II.A and III.B we describe the details of the theoretical modeling and experiments, respectively. In Section II.A and III.B the structural, electronic and magnetic properties of SCIO are compared to those of the end members. Furthermore, in III.C and III.D a detailed analysis of the orbital occupation and optical properties as a function of strain is provided. The calculated absorption coefficients are compared with transmission measurements on strained SCIO films. Finally, the results are summarized in Section IV.

II. METHODS

A. Computational details

The density functional theory (DFT) calculations were performed with the VASP [31, 32] code using the projector augmented wave (PAW) method [33]. We chose the PBEsol [34, 35] exchange-correlation functional, which is known to improve the structural description of solids as compared to PBE [36]. The following valence electron configuration was used: 4s$^1$3d$^8$ for Co, 6s$^2$5d$^8$ for Ir, 4s$^2$4p$^5$5s$^2$ for Sr and 2s$^2$2p$^4$ for O. To account for static electronic correlations we included a Hubbard $U$ term, using the Dudarev approach [37]. We summarize here previously used $U$ values for related compounds, but note that values applied or obtained with different codes are not directly comparable [38, 39]: $U_{Co} = 5.44$ eV and $U_{Ir} = 2.77$ eV, $J_{Co} = 0.918$ eV and $J_{Ir} = 0.544$ eV from [12] were chosen in a previous study of SCIO [24] with the WIEN2k code [40]. For SCO the values previously used in VASP calculations range from $U_{Co} = 2.5$ eV and $J_{Co} = 1.0$ eV [10] to $U_{Co} = 6$ eV [41]. While element specific $U$ values in general depend on the local environment and oxidation state [42], for consistency and comparability we selected here the same $U$ values for the DP and the end members: $U = 3.0$ eV for the Co ion, in order to describe correctly the FM metallic ground state of bulk SCO, as discussed below, as well as $U = 1.37$ eV, $J = 0.22$ eV for Ir, obtained from the constrained random phase approximation with the VASP code for SIO [20]. Additional calculations were performed with the Liechtenstein [43] approach, to ensure that the results of both approaches are consistent. In the following we discuss the ones obtained with the Dudarev approach.

The wave functions were expanded in a plane-wave basis truncated at 600 eV. For SrCoO$_3$ and SrIrO$_3$ a 20-atom unit cell was used ($\sqrt{2a} \times \sqrt{2a} \times 2c$), whereas a 40-atom unit cell was employed for Sr$_2$CoIrO$_6$ in a $2a \times 2a \times 2c$ setup in order to model the cation and magnetic arrangement (see Fig. 1). To sample the Brillouin zone, $8 \times 8 \times 6$ k-points shifted off $\Gamma$ were generated using the Monkhorst-Pack scheme [44] for SrCoO$_3$ and SrIrO$_3$, and $5 \times 5 \times 5$ k points were used for the double perovskite Sr$_2$CoIrO$_6$. The convergence criterion for the self-consistent calculation is $10^{-6}$ eV for the total-energy. A Fermi smearing of 0.05 eV is used for the geometry optimization and the further analysis. For SrCoO$_3$ and SrIrO$_3$, all atomic positions and unit cell parameters were optimized until the atomic forces were less than 0.01 eV/Å. For the strained DP Sr$_2$CoIrO$_6$ all atomic posi-
tions and the c-lattice constant were optimized.

The optical spectrum of the strained double perovskite SCIO was obtained within the I.P. approximation. Additionally, quasiparticle effects were considered with a single shot $G_0W_0$ calculation [28] and excitonic effects by solving the BSE [29, 30]. For the calculation of the real and imaginary part of the dielectric function we used 50 frequency grid points with a cut-off energy of 600 eV. A total of 48 valence and 54 conduction bands were employed for the calculation of the BSE spectrum, which ensures convergence of the spectrum up to at least 3 eV. A Gaussian broadening of 0.1 eV is used for the I.P. and $G_0W_0$ spectrum and 0.05 eV for the BSE spectrum.

### B. Experimental details

The SCIO thin films investigated in this study were grown by the MAD technique on various pseudocubic (pc) (001) oriented substrates. MAD employs an oxygen-rich growth atmosphere and enables to prepare high-quality perovskite thin films [46–48]. To protect the thin films from environmental degeneration, a STO capping layer was grown also by MAD directly after the SCIO film. The characterization of each sample, in particular, phase purity, degree of B-site ordering and degree of strain transfer, was done by room-temperature x-ray diffraction (XRD, XRR and RSM), far-field Raman spectroscopy and high-resolution scanning transmission electron microscopy: reciprocal space maps (RSMs) around the (013)$_{\text{pc}}$ substrate peak in combination with HAADF STEM images in [100]$_{\text{pc}}$ direction confirm the fully strained state of the SCIO thin films. The degree of B-site ordering was analyzed by XRD scans in tilted geometry as well as by polarization-dependent Raman spectroscopy. Together with HAADF STEM images in [110]$_{\text{pc}}$ direction of selected samples they indicate at least 65% Co/Ir ordering. For more details on the characterization see Ref. [25].

The optical properties of SCIO, deposited on three different substrates [(LaAlO$_3$)$_{0.3}$(Sr$_2$TaAlO$_6$)$_{0.7}$ (LSAT), STO, and GSO], were investigated by optical transmission spectroscopy in vacuum, using a Bruker IFS 66v/S Fourier-transform infrared spectrometer. In order to cover the wide energy range of interest, we employed different detectors (silicon (Si), germanium (Ge), and mercury cadmium telluride (MCT)) and different beamsplitters (quartz and KBr). The spectra for the different energy regions were subsequently stitched together, using appropriate scaling factors, to obtain a single spectrum covering the energy range from 0.3 eV to 2.6 eV. To obtain the energy-dependent absorption coefficient, we used Lambert-Beer’s law: $\alpha = -\ln(I/I_0)$, where $I$ is the transmission of the sample and $I_0$ is the transmission through a reference sample, i.e. a substrate without the SCIO layer. The resulting absorption spectra (see Fig. 10), exhibit an almost linearly increasing background signal, leading to a slightly tilted spectrum. This background signal stems most likely from deviations between the reference and the SCIO sample including the STO capping layer and could not be reduced in these measurements.

### III. RESULTS AND DISCUSSION

#### A. Structural and magnetic properties

![FIG. 2. The total energy of SrCoO$_3$ with FM and AFM order for different symmetry for $U = 1.5$ eV, 3.0 eV and 4.52 eV.](image)

The structural, electronic and magnetic properties of the three compounds obtained from the DFT+$U$ calculations without and with SOC are summarized in Table I and [1] respectively. We begin the discussion with the end members SrCoO$_3$ and SrIrO$_3$, before turning to the double perovskite Sr$_2$CoIrO$_6$.

For SCO we considered the tetragonal phases (P4/mmb and P4/mmm) proposed in a previous PBE+$U$ study [7], however, full structural optimization rendered an orthorhombic $Pmc2_1$ phase, 0.57 and 0.56 eV per simulation cell more stable than the tetragonal ones. Furthermore, the magnetic order of the ground state is sensitive to the Hubbard $U$ parameter: The energetic stability of the different phases, plotted in Fig. 2 as a function of $U$, shows that ferromagnetic coupling is favored for $U \leq 3eV$, but for higher values it switches to a G-type antiferromagnetic state, with significant B-site off-centering, likely related to the AFM ferroelectric phase predicted by Lee and Rabe [10]. Since the ground state of SCO is FM metallic [6], we proceed the further analysis using $U = 3$ eV for Co. The band structure, projected density of states (PDOS) and spin density for the FM and AFM phases is displayed in Fig. 3. For $U = 3$ eV, the FM metallic state is preferred by 0.40 eV compared to the AFM-G insulating phase, with Co in an intermediate spin state ($t_{2g}^{4}e_{g}^{1}$) with a magnetic moment of 2.51 and 2.85 $\mu_B$ for the FM and AFM phases, respec-
FIG. 3. DFT+U band structure (a), (b) without and (c), (d) with SOC, element-projected density of states (PDOS) and (e), (f) spin density of SrCoO$_3$ for FM (top panels) and G-type AFM coupling (bottom panels). Majority and minority bands in (a) and (b) are shown in dark grey and orange, respectively.

TABLE I. The DFT+U values of lattice constants, band gaps, spin moments, out-of-plane and in-plane bond angle and bond length for SrCoO$_3$, SrIrO$_3$ and strained Sr$_2$CoIrO$_6$, without spin-orbit coupling (SOC). For comparison we list also the measured $c_{\text{exp}}$ from Ref.[25].

datively. Including spin-orbit coupling, Co acquires an orbital moment of 0.13 $\mu_B$ (FM) and 0.09 $\mu_B$ (AFM). Furthermore, the [110]-magnetization direction is favored by 8.34 meV over [001]. Concerning the structural properties, SCO shows noticeable octahedral tilts (cf. Fig. 1a) expressed in a reduction of the in-plane and out-of-plane Co-O-Co angles to 173° and 171°, respectively, whereas the in- and out-of-plane Co-O bond lengths are 1.92 and 1.90 Å, respectively. For the AFM-G phase three distinct bond lengths are obtained: 1.80 and 2.12 Å in-plane and 1.89 Å out-of-plane.

The other end member, SIO, exhibits a $Pbnm$ structure with an (a$^\perp$ a$^\perp$ c$^\perp$) tilt pattern in Glazer’s notation and a strongly reduced Ir-O-Ir bond angle of
the system is semimetallic with a fully occupied j band structure the same color scheme was used as in Fig. 3.

SrIrO$_3$ and SrTiO$_3$ are closely related to the electronic reconstruction and a switching of the magnetic easy axis. While our results do not show a reversal, the energy difference between the preferred [100]-magnetization direction over the [001] decreases from 85 meV to 70 meV per 40-atom u.c. from compressive to tensile strain.

B. Electronic properties

We now turn to the electronic properties. Figs. 3 and 5 display the band structure, total and element-projected DOS with and without SOC for the end members SCO, SIO and the strained double perovskite SCIO, respectively. As mentioned above, SrCoO$_3$ is a ferromagnetic metal (Fig. 3a and c), whereas the G-type AFM phase (Fig. 3b and d) has an indirect band gap of 220 meV with the top of the valence band at X and the bottom of the conduction band at S.

SrIrO$_3$ is a metal that turns into a semimetal with a dip of the DOS at the Fermi level upon charge transfer, that will be discussed in subsection [III.D].

SCIO is an antiferromagnetic insulator, 0.50-0.57 eV per simulation cell more favorable than the ferromagnetic phase. The AFM configuration comprises mixed Co, Ir planes that couple antiparallel along the [110]-direction, as can be seen from the spin density plotted in Fig. 5g-i. This configuration was found to be more stable than AFM order along the [111] or [001]-directions in preliminary calculations [49] with the WIEN2k code [41], and is consistent with the magnetic order determined from neutron powder diffraction. [21]. The spin moment of Co in SCIO (~ 2.74 $\mu_B$) is comparable to the one in bulk SCO (2.51 $\mu_B$ (FM) and 2.85 $\mu_B$ (AFM)) and close to the experimental (2.6(1) $\mu_B$) and theoretical value (~ 3.00 $\mu_B$) reported in Ref. [24]. Most interestingly, Ir acquires a significant magnetic moment of 1.31 – 1.38 $\mu_B$, compared to the zero magnetic moment in bulk SIO and at variance with a vanishing contribution of Ir suggested from experiment [21] (the theoretical value from that study is ~ 0.81 $\mu_B$). The origin of this effect will be discussed in the next subsection. Including SOC, the spin moments of both ions are somewhat reduced and show a weak dependence on strain: 2.35-2.45 $\mu_B$ for Co and 1.21-1.25 $\mu_B$ for Ir with increasing lateral lattice constant. At the same time the orbital moments are substantially enhanced w.r.t. the end members and vary between 0.31-0.46 $\mu_B$ for Co (the latter at $a_{STO}$) and 0.14-0.13 $\mu_B$ for Ir. Recent XAS measurements [25] suggest a switching of the magnetic easy axis. While our results do not show a reversal, the energy difference between the preferred [100]-magnetization direction over the [001] decreases about 0.35 meV from compressive to tensile strain.

FIG. 4. DFT+$U$ band structure and element-projected density of states of SrIrO$_3$ (a) without and (b) with SOC. For the band structure the same color scheme was used as in Fig. 3.
FIG. 5. DFT+U band structure, projected density of states (PDOS) and spin density of Sr$_2$CoIrO$_6$ (a)-(c) without and (d)-(f) with SOC strained at: (a) and (d) $a_{NGO}$, (b) and (e) $a_{STO}$, (c) and (f) $a_{GSO}$. For the band structure the same color scheme was used as in Fig. 3.

In contrast, the strained DP SCIO this degeneracy is lifted. In particular the band width of the $e_g$ states is enhanced for compressive strain, even stronger for the $d_{x^2-y^2}$-orbital, that extends to lower energies at $a_{NGO}$, whereas at $a_{GSO}$ the bottom of the $d_{x^2}$-band lies lower. The position and occupation of Co 3$d$-bands changes significantly from SCO to SCIO: while the narrow unoccupied part of the $t_{2g}$ bands in the majority spin-channel of SCO lies between 0.2 and 1.1 eV and the broader $e_g$ bands between 1-3 eV, in SCIO the former splits into an occupied part just below $E_F$ and an unoccupied fraction shifted to $\sim 1.5$ eV. Likewise, the empty $e_g$ bands broaden and move upwards, ranging between 1.5 and 5.4 eV. The orbitally- and spin-resolved d-band centers, calculated according to Ref. [50] are also displayed in Fig. 6 and show an upward shift both for Co and Ir compared to the end members. The d-band centers allow also a qualitative comparison to the level diagram resulting from the x-ray absorption spectra in Ref. [25]: specifically, the band center of the $d_{xy}$ orbital lies higher for compressive strain but a downward shift and reversal of sequence takes place for tensile strain, which is consistent with Ref. [24].

A strong electronic rearrangement is observed for Ir in SCIO compared to the end member SIO, as shown in Fig. 6: In SIO the PDOS around $E_F$ is dominated by the partially occupied and degenerate $t_{2g}$ states in both spin channels, whereas the unoccupied $e_g$ bands extend between 1.3 and 5.3 eV. In contrast, in SCIO the latter move upwards and are narrower, lying between 1.6 and 5 eV. More severe changes occur for the $t_{2g}$ states: in one spin channel the unoccupied part splits off and shifts upwards localized between 0.17 and 0.88 eV, whereas in the other the $t_{2g}$ bands are fully occupied. The substantial spin splitting (also for the $e_g$ bands) and imbalance in occupation of the $t_{2g}$ states explains the emergence of a significant spin moment at the Ir-sites of $\sim 1.3$ $\mu_B$, as compared to the nonmagnetic SIO. The effect of strain on
the occupied Ir $t_{2g}$ bands is similar to the one on Co: the $d_{xy}$ and $d_{xz}$ orbitals prevail at the bottom of the $t_{2g}$ band for compressive and tensile strain, respectively, whereas the $d_{z^2}$ states get narrower for tensile strain. Similar effects are observed when including SOC, the major difference being the emergence of semimetallic behavior for bulk SIO when SOC is switched on.

C. Quantification of charge transfer

Both the emergence of a substantial moment of $\sim 1.3 \ \mu_B$ at the Ir sites and the analysis of the orbitally-projected DOS above signal strong rearrangement in occupation and charge transfer at the Co and Ir sites in SIO in comparison to the end members. To quantify the charge transfer we have plotted in Figs. 7 and 8 the change in Co 3$d$ and Ir 5$d$ orbital occupation in SIO w.r.t. the end members without and with spin-orbit coupling. The main effect is a strong reduction of occupation by $\sim 0.75e^-$ in the Ir $t_{2g}$ minority spin channel which is transferred partially ($\sim 0.58e^-$) to the majority spin orbitals of Ir (mainly $t_{2g}$, to a lesser extent $e_g$) and to Co ($\sim 0.15e^-$). The latter effect is weaker than the previously proposed valence change from 4+ in the bulk end members to a Co$^{3+}$ and Ir$^{5+}$ configuration $[23, 25, 26]$ in SIO. In contrast to the Ir 5$d$ orbitals, the Co 3$d$ occupation reveals substantial orbital dependence in the minority spin channel (the majority being filled): both $e_g$ orbitals exhibit a reduction by $0.22e^-$ ($d_{x^2-y^2}$) and $0.30e^-$ ($d_{z^2}$), respectively. Simultaneously, the minority-spin $t_{2g}$ states occupation is enhanced, showing also a pronounced strain-dependence: while the $d_{xy}$-occupation increases by 0.28 to 0.38 by 0.28 to 0.38 from compressive to tensile strain, the other two increase by 0.19 to 0.14 ($d_{xz}$) by 0.0.15 to 0.11 ($d_{yz}$). Remarkably, these orbitally resolved changes with strain largely compensate in the total $d$ occupation, which shows no notable strain dependence.

The changes in orbital occupation with SOC (Fig. 8) are consistent with the trends observed for the case without SOC and highlight the opposite tendency for Ir and Co: for the $t_{2g}$ orbitals there is a gain in occupation for
FIG. 7. Changes in occupation number of the five Co 3d (blue) and Ir 5d (yellow) orbitals in SCIO with respect to the occupation number in the end members SCO, SIO without SOC as a function of strain. Solid and empty symbols represent changes in occupation numbers for spin up and spin down states, respectively.

FIG. 8. Changes in occupation number of the five Co 3d (blue) and Ir 5d (yellow) in SCIO with respect to the occupation number in the end members SCO, SIO with SOC as a function of strain. Co (0.15-0.23 e\(^{-}\) for \(d_{xy}\), 0.22-0.21 e\(^{-}\) for \(d_{xz}\), and 0.27-0.17 e\(^{-}\) for \(d_{yz}\)) and loss for Ir (-0.15 for \(d_{xy}\), -0.14 e\(^{-}\) for \(d_{xz}\) and \(d_{yz}\)), this trend is reversed for the \(e_g\) states: Ir shows a weak enhancement of 0.15 e\(^{-}\) each, whereas Co a reduction in electron count (\(\sim 0.24 e\(^{-}\) each). The total \(d\) occupation indicates a net charge transfer of 0.15 e\(^{-}\) from Ir to Co.

To visualize the electronic reconstruction as well as the involvement of the ligands, we have plotted in Fig. 9 the spatial distribution of the unoccupied states integrated between the Fermi level and 6.0 eV without SOC (isosurface value is 0.06 e\(^{-}\) Å\(^{-3}\)) for (a) the end member SrCoO\(_3\) for G-AFM coupling and (b) the double perovskites (b) SCIO at \(a_{NGO}\) as a representative example.

D. Optical properties

The optical properties of the strained double perovskite SCIO are assessed in the I.P. approximation, as well as including quasiparticle and excitonic effects by performing a \(G_0W_0\) and BSE calculation for the case without SOC. The real and imaginary parts of the dielectric tensor are displayed in Fig. 10. Additionally, in the lower panels the absorption coefficient, derived from Re\[\varepsilon(\omega)\] and Im\[\varepsilon(\omega)\], is compared to the one obtained from transmission measurements.

To explore the effect of strain, the in- and out-of-plane components of Re\[\varepsilon(\omega)\] and Im\[\varepsilon(\omega)\] are plotted with solid and dashed lines, respectively, in Fig. 10. The spectrum obtained within the I.P. approximation, exhibits a two-peak structure with the first peak at \(\sim 1.2\) eV and the second at \(\sim 2.0-2.4\) eV. Recalling the band structure in Fig. 5 and the orbitally projected DOS in Fig. 6 we conclude that the first peak corresponds to transitions between the top of the valence band and the narrow unoccupied \(t_{2g}\) states that extend between 0.16-1.0 eV, whereas the second peak originates from transitions to the broader \(e_g\) states above 1.7 eV. At \(a_{NGO}\) the first peak in Im\[\varepsilon_{xx}(\omega)\] is predominant, more than two times higher than the second and than the peaks of Im\[\varepsilon_{zz}(\omega)\]. In the latter the second peak is slightly more pronounced than the first and is also shifted to higher energy. The main effect of strain is the decrease of the height of the first peak from compressive to tensile strain, thus decreasing the peak height difference in Im\[\varepsilon_{xx}(\omega)\] and also
FIG. 10. (a)-(c) Real and (d)-(f) imaginary part of the dielectric tensor within the I.P. (blue line), $G_0W_0$ (petrol line) and $G_0W_0+BSE$ (red line) approximations for SCIO strained at (a), (d) $a_{NGO}$, (b), (e) $a_{STO}$ and (c), (f) $a_{GSO}$. The in- and out-of-plane components are denoted by solid and dashed lines, respectively. (g)-(i) The absorption coefficient in comparison with the one obtained from transmission measurements (black line). We note that in experiment for compressive strain a sample grown on an LSAT substrate was used instead of NGO, however both have similar (pseudocubic) lattice constant: $a_{LSAT} = 3.868 \text{ Å}$ vs. $a_{NGO} = 3.855 \text{ Å}$, respectively [25].

Inclusion of quasiparticle effects within the $G_0W_0$ approximation shifts the spectrum to higher energies by $\sim 0.34$ eV, and lowers the height of the second peak in $\text{Im}[\varepsilon_{zz}(\omega)]$, the opposite effect occurs for $\text{Im}[\varepsilon_{xx}(\omega)]$, where the second peak prevails. Excitoning effects, considered by solving the Bethe-Salpeter equation lead to a redshift of the spectrum. Additionally, the height of the first peak in $\text{Im}[\varepsilon_{xx}(\omega)]$ is reduced and the second peak is suppressed, yielding only one main peak, followed by a broader plateau. On the other hand, $\text{Im}[\varepsilon_{zz}(\omega)]$ exhibits a slightly more pronounced first peak, whose height is $\sim 50\%$ of the one of $\text{Im}[\varepsilon_{xx}(\omega)]$ and decreases for $a_{STO}$ and subsequently increases for $a_{GSO}$.

As discussed previously, the band gap in the I.P. case shows a nonmonotonic behavior as a function of strain: 0.163 eV ($a_{NGO}$), 0.235 eV ($a_{STO}$) and 0.187 eV ($a_{GSO}$). Including quasiparticle effects leads to a blueshift of the spectrum to higher energies, increasing the band gap to 0.503 eV ($a_{NGO}$), 0.576 eV ($a_{STO}$) and 0.529 eV ($a_{GSO}$). Upon taking into account excitonic effects by solving the BSE, spectral weight is redistributed to lower energies and the onset of the spectrum lies between the ones for I.P. and $G_0W_0$ at 0.352 eV ($a_{NGO}$), 0.458 eV ($a_{STO}$) and 0.386 eV ($a_{GSO}$).

To enable a comparison with experiment, in Fig. 10 (g)-(i) we plot the absorption coefficient. Within I.P. the in-plane absorption coefficient shows a two peak structure with a comparable size of the peaks, whereas the out-of-plane coefficient has rather a two-plateau shape. The relative height difference between the in- and out-of-plane coefficient is reduced as the biaxial strain changes from compressive to tensile. While $G_0W_0$ leads mainly to a blueshift of the spectrum, subsequent inclusion of excitonic effects redshifts slightly the spectrum and suppresses the second peak in $\alpha_{xx}$ to rather a broad plateau and a more predominant first peak. The two-plateau shape of the out-of-plane coefficient is preserved. The transmission spectra are measured with an incidence angle perpendicular the sample surface. The vector of the electric field is thus almost parallel to the sample surface and therefore also yielding mainly an in-plane contribution. The overall shape of the measured spectrum, in particular the two-plateau feature, as well as the decrease in absorption with strain is in line with the simulation. We note that a direct comparison between the calculated and measured spectrum should be taken with caution as the theoretical spectrum is performed for the strained ordered bulk phase, whereas in the measured samples SCIO is grown as a thin film on different substrates with a SrTiO$_3$ capping layer. Thus interfacial effects both to the substrate and the capping layer as well as effects of cation disorder, that are not explicitly considered in the calculation, potentially lead to a reduced band gap and an early onset of the measured spectrum, while the first peak in the simulation lies at higher energies. On the other hand, the $G_0W_0+BSE$ spectrum renders a good agreement concerning the position of the second peak/plateau at $\sim 2.6$ eV, signifying the importance of many body effects.
IV. CONCLUSION

Based on density functional theory calculations taking into account a Hubbard $U$ term and spin-orbit coupling, we present a comprehensive investigation of the structural, electronic, magnetic and optical properties of the double perovskite SCIO in comparison to the end members SCO and SIO. While SCO is a ferromagnetic metal and SIO a nonmagnetic semimetal, SCIO is an antiferromagnetic insulator with a Co spin and orbital moment of $\sim 2.4$ and $0.3 \mu_B$, respectively, and most remarkably, a significant spin and orbital moment of Ir of $\sim 1.2$ and $0.13 \mu_B$. Analysis of the orbital occupation w.r.t the end members confirms a considerable electronic reconstruction and a charge transfer from the Ir minority to majority spin states, rendering a substantial magnetic moment and a charge transfer from the Ir minority to major-
