Clinical value of liver and spleen shear wave velocity in predicting the prognosis of patients with portal hypertension

Yan Zhang, Da-Feng Mao, Mei-Wu Zhang, Xiao-Xiang Fan

AIM
To explore the relationship of liver and spleen shear wave velocity in patients with liver cirrhosis combined with portal hypertension, and assess the value of liver and spleen shear wave velocity in predicting the prognosis of patients with portal hypertension.

METHODS
All 67 patients with liver cirrhosis diagnosed as portal hypertension by hepatic venous pressure gradient in our hospital from June 2014 to December 2014 were enrolled into this study. The baseline information of these patients was recorded. Furthermore, 67 patients were followed-up at 20 mo after treatment, and liver and spleen shear wave velocity were measured by acoustic radiation force impulse at the 1st week, 3rd month and 9th month after treatment. Patients with favorable prognosis were assigned into the favorable prognosis group, while patients with unfavorable prognosis were assigned into the unfavorable prognosis.
The variation and difference in liver and spleen shear wave velocity in these two groups were analyzed by repeated measurement analysis of variance. Meanwhile, in order to evaluate the effect of liver and spleen shear wave velocity on the prognosis of patients with portal hypertension, Cox’s proportional hazard regression model analysis was applied. The ability of those factors in predicting the prognosis of patients with portal hypertension was calculated through receiver operating characteristic (ROC) curves.

RESULTS
The liver and spleen shear wave velocity in the favorable prognosis group revealed a clear decline, while those in the unfavorable prognosis group revealed an increasing tendency at different time points. Furthermore, liver and spleen shear wave velocity was higher in the unfavorable prognosis group, compared with the favorable prognosis group; the differences were statistically significant ($P < 0.05$). The prognosis of patients with portal hypertension was significantly affected by spleen hardness at the 3rd month after treatment [relative risk (RR) = 3.481]. At the 9th month after treatment, the prognosis was affected by liver hardness (RR = 5.241) and spleen hardness (RR = 7.829). The differences between these two groups were statistically significant ($P < 0.05$). The ROC analysis revealed that the area under the curve (AUC) of spleen hardness at the 3rd month after treatment was 0.644, while the AUCs of liver and spleen hardness at the 9th month were 0.579 and 0.776, respectively. These might predict the prognosis of patients with portal hypertension.

CONCLUSION
Spleen hardness at the 3rd month and liver and spleen shear wave velocity at the 9th month may be used to assess the prognosis of patients with portal hypertension. This is hoped to be used as an indicator of predicting the prognosis of patients with portal hypertension.

Key words: Liver cirrhosis; Portal hypertension; Liver and spleen shear wave velocity; Acoustic radiation force impulse

Core tip: Sixty-seven patients with liver cirrhosis with portal hypertension were assessed by acoustic radiation force impulse imaging at different time points after treatment. We found that the portal hypertension was significantly affected by spleen hardness at the 3rd month after treatment [relative risk (RR) = 3.481]. At the 9th month after treatment, the prognosis was affected by liver hardness (RR = 5.241) and spleen hardness (RR = 7.829). ROC analysis revealed that the area under the curve of liver and spleen hardness might be used to predict the prognosis of patients with portal hypertension.

World J Gastroenterol 2017; 23(45): 8044-8052. Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i45/8044.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i45.8044

INTRODUCTION
Portal hypertension is a common cause of cirrhosis and presents a series of symptoms [1-3]. In recent years, with the increase in incidence of liver cirrhosis, the number of patients with portal hypertension has rapidly increased [4]. The main clinical manifestations of portal hypertension are hepatosplenomegaly and ascites, which bring great negative impact on patients [5]. Due to its hard texture and obvious symptoms, splenomegaly associated with portal hypertension is significantly different from others, and is regarded as one of the main features of portal hypertension [6-7]. In clinical practice, severe complications of portal hypertension, including gastric fundus, esophageal varices, hepatic encephalopathy and gastrointestinal bleeding, have increased the risk of exacerbation, and even death [8-11]. In order to avoid complications and reduce the mortality of patients, early and effective evaluation indicators should be developed for predicting the prognosis.

As a new technology of ultrasonic elastography, acoustic radiation force impulse (ARFI) imaging can quantitatively reflect the advantages of tissue hardness by detecting the degree of deformation of the organ after compression, in order to assess the elasticity and hardness of tissues [12-15]. These detected results are displayed through imaging [16,17]. Although the clinical value of ARFI in predicting liver fibrosis, tumors and other diseases has been confirmed [18,19], researches on ARFI for detecting portal hypertension caused by cirrhosis have not been studied in detail. Hence, it remains to be determined whether ARFI has the ability to detect and evaluate portal hypertension prognosis.

Therefore, in this study, liver and spleen ARFI shear wave velocity values were determined to evaluate the clinical significance of ARFI for detecting portal hypertension caused by liver cirrhosis in patients, aiming to provide predictive indications for the prognosis of patients and avoid complication and death.

MATERIALS AND METHODS

Study objective
A total of 67 patients with liver cirrhosis, who were diagnosed with portal hypertension by hepatic venous pressure gradient (HVPG) in our hospital from June 2014 to December 2014, were included in this study. Among these patients, 42 were male and 25 were female; age of these patients ranged within 20-70 years old, with an average age of 52.68 ± 7.43 years-old. This research was approved by the Ethics Committee of our hospital, and all patients provided a signed informed consent.
Inclusion and exclusion criteria

Inclusion criteria: (1) patients diagnosed with liver cirrhosis through clinical symptoms combined with laboratory or image examinations; (2) patients with HVPG ≤ 12 mmHg; and (3) patients classified as grade A or B in the Child-Pugh grading criteria.

Exclusion criteria: (1) patients whose shear wave velocity values could not be acquired by ARFI; (2) patients with liver cancer or other complications; (3) patients with acute heart failure, cardiogenic shock, or other vital organs diseases; (4) patients who underwent splenic surgery; (5) patients whose hepatosplenomegaly was caused by acute infection and other reasons; and (6) patients who were receiving propranolol hydrochloride or other drugs that can affect portal pressure.

Instruments and methods

All 67 patients underwent routine clinical examinations at the day of hospitalization, and the serological indicators of liver function and clinical symptoms of these patients were recorded. After treatment, liver and spleen ARFI shear wave velocity was measured continuously for all patients for 1 wk, and the results were recorded. Patients were instructed to fast at least 8 h before the measurement. A Siemens Acuson S2000 ultrasound system was used with a 4C1 convex array probe. During the liver shear wave velocity measurement, patients were asked to completely hold their breath and lie on the right side (Figure 1A). The probe was kept vertically fixed on the intercostal space to avoid larger blood vessels. This was repeated three times, and measurement results averaged. During the spleen shear wave velocity measurement, patients were instructed to hold their breath and lie on their left side (Figure 1B). These steps were repeated and the mean shear wave velocity values were recorded.

Follow-up

All 67 patients were followed-up for 20 mo after treatment. The first follow up was at the 1st month, and subsequent follow ups were performed by telephone every 3 mo. At the 3rd and 9th month, the liver and spleen ARFI shear wave velocity values of patients were measured, and the results were recorded. The endpoint of this study was the unfavorable prognosis of patients during the follow-up period, which include complications or death after treatment. After the follow ups, initial results upon admission and results of the last follow up were collected. In addition, the number of patients with unfavorable prognosis, serological indicators, the liver and spleen shear wave velocity values at the 1st week and at the 3rd and 9th month after treatment, and the diagnosis of the physician were recorded. Patients who were lost, refused visit, quit or died from other causes unrelated to the study were defined as censored.

Data processing after follow-up

During the 20-mo follow-up period, patients with favorable prognosis were assigned into the favorable prognosis group, while patients with unfavorable prognosis were as assigned into the unfavorable prognosis group. At the end of the follow-up period, baseline information, prognosis results, serological indicators of liver function, and liver and spleen ARFI shear wave velocity measurements were analyzed. The baseline information of patients included age and sex. The prognosis results were classified as either favorable prognosis or unfavorable prognosis. The serological indicators of liver function included albumin (ALB), alanine aminotransferase (ALT) and aspartate aminotransferase (AST).

Statistical analysis

SPSS 19.0 was used for statistical analysis. Shear wave velocity values, and the values of serological indicators ALB, AST and ALT and other measurement data were presented as mean ± SD. The unfavorable prognosis rate of patients and follow-up results were expressed via survival curve and pie chart, respectively, to analyze the prognosis of patients with portal hypertension. The variation and difference of shear wave velocity values in these two groups at the 1st week and the 3rd week.
and 9th month after treatment were compared using repeated measures analysis of variance to explore the relationship between shear wave velocity values at different time points and portal hypertension. Age, sex, prognosis results, ALT, ALB and AST, shear wave velocity values and other possible influences were included in the Cox’s proportional hazard regression model analysis. and indicators that affected prognosis were selected. On this basis, the receiver operating characteristic (ROC) curve was used to further compare with the area of all indicators that have statistically significant differences the area under the curve (AUC), and to investigate the ability of indicators that could predict the prognosis of patients with portal hypertension. \( P < 0.05 \) was considered statistically significant.

**RESULTS**

**Analysis of follow-up results and unfavorable prognosis rate**

The follow-up results revealed 29 patients in the favorable prognosis group and 34 patients in the unfavorable group. Among these patients, 11 patients died, 60 patients had adverse complications, and 4 patients were lost to follow-up. The Kaplan-Meier survival curve was used to analyze the incidence of portal hypertension complications after treatment. Results revealed that the unfavorable prognosis rate was 58.97\%, as shown in Figures 2 and 3.

**Comparison of liver shear wave velocity values between the favorable prognosis group and unfavorable prognosis group**

The analysis results of variations in liver shear wave velocity values revealed that the liver shear wave velocity value in the unfavorable prognosis group exhibited an increasing trend, while a clear decline was observed in the favorable prognosis group (\( F_{within\ group} = 2.106, P_{within\ group} = 0.039 \)). The liver shear wave velocity value was highest at the 1st week after treatment in the favorable prognosis group, which gradually decreased thereafter. This value was lowest at to 9th month after treatment. However, in the unfavorable prognosis group, the liver shear wave velocity value was highest at the 9th month and lowest at the 1st week after treatment.

The liver shear wave velocity values of these two groups were compared among different time points. Although, these values in the favorable prognosis group were slightly higher than those in the unfavorable prognosis group and the difference was not statistically significant (\( P > 0.05 \)). Furthermore, the difference in liver shear wave velocity values at the 3rd and 9th month was statistically significant (\( P < 0.05 \)), and these values in the favorable prognosis group were lower. Overall, the liver shear wave velocity values in the unfavorable prognosis group were higher than those in the favorable prognosis group, and the difference was statistically significant (\( F_{between\ groups} = 2.193, P_{between\ groups} = 0.032 \)). Furthermore, these values correlated between the different groups or among different times points (\( F_{interaction} = 2.457, P_{interaction} = 0.017 \) (Table 1).

**Comparison of spleen shear wave velocity values between the favorable prognosis group and unfavorable prognosis group**

In the favorable prognosis group, the spleen shear wave velocity values declined from the 1st week to the 9th month after treatment. The value at the 1st week was highest and the value at the 9th month was lowest. However, spleen shear wave velocity values in the unfavorable prognosis group exhibited an increasing trend. The minimum and maximum values of the liver shear wave velocity were reached at the 1st week and 9th month after treatment, respectively. Values at the different time points of these two groups are presented in Table 2.

These results revealed that spleen shear wave velocity values at the 3rd and 9th month in the unfavorable prognosis group were higher, and the difference was statistically significant (\( P < 0.05 \)). Furthermore, values at the 1st week in these two groups
were similar, and the difference was not statistically significant ($P > 0.05$). The spleen shear wave velocity values were compared between these two groups. These results revealed that values in the unfavorable prognosis group were higher than in the favorable prognosis group, and the difference was statistically significant ($F_{\text{between groups}} = 8.431$, $P_{\text{between groups}} = 0.000$). The values in different groups or at different time points were correlated ($F_{\text{interaction}} = 3.422$, $P_{\text{interaction}} = 0.001$).

**Evaluation of the effects of suspicious indicators using the Cox’s proportional hazard regression model**

A Cox’s proportional hazard regression model was constructed to analyze the effects of all suspicious indicators on portal hypertension prognosis. These results revealed that the age and sex of patients had no effect on prognosis ($P > 0.05$), and serological indicators including ALB, AST and ALT did not influence the prognosis. At the same time, all liver and spleen shear wave velocity values at different time points were evaluated, and results revealed that liver shear wave velocity values at the 9th month and spleen shear wave velocity values at the 3rd and 9th month could affect the prognosis of patients ($P < 0.05$); other values had no significant effects ($P > 0.05$). All indicators that had statistically significant differences were compared. The spleen shear wave velocity value at the 9th month after treatment had the strongest effect on the prognosis of patients (relative risk (RR) = 8.829). The liver hardness value at the 9th month ranked second (RR = 6.271), followed by the spleen hardness value at the 3rd month (RR = 3.481), as shown in Table 3.

**Comparison of the ability of liver shear wave velocity values at the 9th month and spleen shear wave velocity values at the 3rd and 9th month for predicting prognosis**

In order to analyze the predictive ability of these three indicators for adverse prognosis, the ROC curve was established. This revealed that the AUC of spleen shear wave velocity values at the 3rd month and the AUC of the liver and spleen shear wave velocity values at the 9th month were 0.644, 0.579 and 0.776, respectively. It was found that the AUC of the spleen shear wave velocity value at the 9th month was highest. The sensitivity was 55.9%, specificity was 89.7% and the best diagnostic value was 0.455. Furthermore, the AUC of the spleen shear wave velocity value at the 3rd month was slightly lower, and the sensitivity, specificity and best diagnostic value was 70.6%, 58.6% and 0.292, respectively. The lowest AUC was the liver shear wave velocity value at the 9th month, and the sensitivity, specificity and best diagnostic value was 73.5%, 48.3% and 0.218, respectively (Figure 4).

**DISCUSSION**

Portal hypertension is a clinical syndrome caused by portal venous drainage obstruction. This occurs in middle-age men and develops slowly, and most of these cases are closely associated with cirrhosis\(^ \text{[25-27]} \). In China, the number of new patients with cirrhosis increase year after year\(^ \text{[23]} \). At the same time, the incidence of portal hypertension has also rapidly increased\(^ \text{[24]} \). The majority of patients often present with liver dysfunction, bleeding, gastrointestinal vascular disease and other serious diseases, except common clinical symptoms, including hepatosplenomegaly and ascites\(^ \text{[25]} \).

At present, the main approaches for the clinical treatment of portal hypertension are surgery and symptomatic treatment\(^ \text{[26]} \). Although these treatment approaches are diverse and effective, the mortality rate of patients who have this disease remains high due to delitescent pathogenetic condition, long disease duration

### Table 1 Comparison of the liver shear wave velocity values of the two groups at the 1st week and at the 3rd and 9th month after treatment

| Group                     | 1st wk after treatment, m/s | 3rd mo after treatment, m/s | 9th mo after treatment, m/s |
|---------------------------|-----------------------------|-----------------------------|-----------------------------|
| Favorable prognosis group | 1.88 ± 0.39                 | 1.70 ± 0.41                 | 1.67 ± 0.38                 |
| Unfavorable prognosis group| 1.84 ± 0.43                | 1.92 ± 0.45                 | 2.08 ± 0.35                 |
| t                         | 0.384                       | 2.068                       | 4.455                       |
| P value                   | 0.702                       | 0.043                       | 0.000                       |

Data are presented as mean ± SD. (1) $F_{\text{within group}} = 2.106$, $P_{\text{within group}} = 0.039$; (2) $F_{\text{between groups}} = 2.193$, $P_{\text{between groups}} = 0.032$; (3) $F_{\text{interaction}} = 2.457$, $P_{\text{interaction}} = 0.017$.

Analysis of unfavorable prognosis rates and the comparison of liver and spleen shear wave velocity values in these two groups

The common adverse complications of portal hypertension include esophageal and gastric variceal bleeding, hepatic encephalopathy, hepatorenal syndrome and others; these are the main indications of surgery for treating portal hypertension. Among these complications, esophageal and gastric variceal bleeding were the most dangerous. When this occurs, patients will be at risk due to acute upper gastrointestinal bleeding. Therefore, it has been considered that the establishment of a prognostic detection system for portal hypertension has clinical value.

In this study, patients were enrolled according to the Child-Pugh criteria and HVPG results. Patients classified as grade C and having an HVPG ≥ 12 mmHg were excluded due to higher risk of surgery, lower survival rate and poor recovery. The Kaplan-Meier survival curve revealed that the unfavorable prognosis rate in all 67 patients was 58.97% at the end of follow-up, which reflects that it is unsatisfactory of the prognosis of patients with portal hypertension. In order to investigate the variation trend of liver and spleen shear wave velocity values, values at three different time points were collected and analyzed by repeated measures analysis of variance. Results revealed that the liver and spleen shear wave velocity values in the favorable prognosis group exhibited a decreasing trend, and there were significant differences in these values at three different time points. Values are lowest in the favorable
Comparative analysis of indicators that affect the prognosis of patients

In order to further investigate indicators that affect the prognosis of portal hypertension, Cox’s proportional hazard regression model was performed on liver function serum markers, clinical data and liver and spleen shear wave velocity values at three different time points. As common clinical detection indicators, liver function serum markers were detected to reflect the degree of liver damage. In this study, ALB, ALT and AST were included in the Cox’s regression model to evaluate their effect on the prognosis of patients with portal hypertension.

Results revealed that liver function serum markers ALB, ALT and AST have no significant effect on the prognosis of this disease. The reasons may be that the variation in ALB, ALT, and AST values are also associated with many diseases such as hepatitis, myocarditis and Japanese B encephalitis, except for cirrhosis. Hence, liver function markers have low sensitivity for the diagnosis and prediction of diseases. Therefore, it is unsatisfactory to take serum markers of liver function as a prognostic indicator of portal hypertension.

On the contrary, in analyzing liver and spleen shear wave velocity values at three different time points, it can be found that the spleen shear wave velocity value at the 3rd month and liver and spleen shear wave velocity value at the 9th month can significantly affect the prognosis of portal hypertension. Among these indicators, the effect of the spleen shear wave velocity value is the most significant, while the value at the 3rd month was the lowest. However, liver and spleen hardness at the 1st week after treatment had no significant effect. This may be due to the improvement of the liver and spleen in the short period after treatment. In addition, the liver shear wave velocity value also has no effect on the prognosis of this disease. The possible reasons are that that liver hardness is not a feature of portal hypertension, this value can be affected by many factors, and the variation degree is similar.

The results of this study show that spleen hardness at the 3rd month and liver and spleen hardness at the 9th month have the potential to assess the prognosis of portal hypertension.

Comparison of the ability of liver and spleen shear wave velocity values at different time points in predicting the prognosis of portal hypertension

Based on the above data, the ROC curve was constructed to further investigate the predictive ability of liver hardness at the 9th month and spleen hardness at the 3rd and 9th month. As a result, the AUC of the spleen shear wave velocity value at the 9th month was highest, which was over 0.7. This revealed that this value had a better predictive ability on the prognosis of portal hypertension, while the AUC of liver hardness at the 9th month and spleen hardness at the 3rd month are lower, and their predictive ability are slightly insufficient. The comprehensive analysis shows that the liver shear wave velocity values at the 9th month and the spleen shear wave velocity values at the 3rd and 9th month are expected to be used as predictive indicators for the prognosis of patients with portal hypertension. Furthermore, this can be combined with other prognosis detection indicators in evaluating the risk of patients.

However, our study still has some deficiency, which includes the small sample data, the inadequate time points for ARFI detection, and the lack of coverage on other types of portal hypertensions. Therefore, future studies with larger samples and adequate detection time points should be conducted to evaluate the other types of portal hypertensions and verify our findings.

In summary, liver and spleen ARFI shear wave velocity values have the potential to monitor the prognosis of portal hypertension, and liver shear wave velocity values at the 9th month and spleen shear wave velocity values at the 3rd and 9th month can reflect the prognosis of patients. It is hoped that this approach could be applied in clinic to reduce complications and improve the survival rate of patients.

COMMENTS

Background

Portal hypertension is a common cause of cirrhosis and presents a series of serious symptoms. In recent years, the incidence rate of liver cirrhosis as well as the portal hypertension rate in China are increasing. The main clinical symptoms of portal hypertension are hepatosplenomegaly and ascites, which bring great negative impact on patients. Because of the hard texture and obvious symptoms, splenomegaly associated with portal hypertension is regarded as one of the main features of portal hypertension. In clinical practice, severe complications of portal hypertension, including gastric fundus, esophageal varices, hepatic encephalopathy and gastrointestinal bleeding, have increased the risk of exacerbation, and even death.

Research frontiers

Acoustic radiation force impulse (ARFI) imaging can quantitatively reflect the advantages of tissue hardness by detecting the degree of deformation of the organ after compression, in order to assess the elasticity and hardness of tissues. These detected results are displayed through imaging. Although the clinical value of ARFI in predicting liver fibrosis, tumors and other diseases has been confirmed, research on ARFI for detecting portal hypertension caused by cirrhosis has not been carried out in detail.
Zhang Y et al. Shear wave velocity predicting the prognosis

Innovations and breakthroughs

ARFI could be used to determine liver and spleen hardness by detecting the degree of deformation of the organ after compression. ARFI is convenient, non-invasive and simple. In this study, we used the technology to figure out the relation between portal hypertension and to try to evaluate the predictive value for portal hypertension.

Applications

The study illustrated the ability for ARFI to be applied to detecting portal hypertension in clinical practice. The prognosis of patients with portal hypertension was significantly affected by spleen and liver hardness. Spleen hardness at the 3rd month, and liver and spleen shear wave velocity at the 9th month may be used to assess the prognosis of patients with portal hypertension. It is expected to be used as an indicator of predicting the prognosis of patients with portal hypertension.

Peer-review

This study illustrated that ARFI imaging could be used in detecting portal hypertension by detecting liver and spleen hardness. Shear wave velocity is a quantitative indicator that is accurate and objective. The detecting process of ARFI is simple, non-invasive, fast and widely used for detection and prediction in clinical practice. Thus, ARFI imaging is a helpful tool that has a significant clinical value and is worthy of developing.
