Abstract.

\textbf{Background:} Cleavage of the amyloid-β protein precursor (AβPP) mediated by host secretase enzymes, releases several fragments including amyloid-β (Aβ\textsubscript{40} and Aβ\textsubscript{42}).

\textbf{Objective:} To determine if \textit{Porphyromonas gingivalis} conditioned medium cleaved AβPP to release Aβ\textsubscript{40} and Aβ\textsubscript{42}.

\textbf{Methods:} The SH-SY5Y cell line was challenged, \textit{in vitro}, with \textit{P. gingivalis} (Pg381) conditioned medium in the presence/absence of cytokines. The cells and their supernatants were assessed for AβPP cleavage fragments by immunoblotting and transmission electron microscopy.

\textbf{Results:} Western blotting of the cell lysates with the anti-AβPP C-terminal antibody demonstrated variable molecular weight bands corresponding to full length and fragmented AβPP in lanes treated with the following factors: Tryptic soy broth (TSB), Pg381, IL-6, Pg381 + IL-1\textbeta, and Pg381 + TNF-α. The low molecular weight bands corresponding to the C99 dimerized fragment were observed in the Pg381 and interleukin-6 (IL-6) treated groups and were significantly more intense in the presence of Pg381 with either IL-6 or TNF-α. Bands corresponding to the dimerized C83 fragment were observed with cells treated with TNF-α alone and with Pg381 combined with IL-1\textbeta or IL-6 or TNF-α. The anti-Aβ antibody detected statistically significant Aβ\textsubscript{40} and Aβ\textsubscript{42}, levels when these two Aβ species were pooled across test samples and compared to the untreated group. Electron microscopic examination of the supernatants demonstrated insoluble Aβ\textsubscript{40} and Aβ\textsubscript{42}.

\textbf{Conclusion:} These observations strongly imply that AβPP is an infection responsive protein cleaved via the amyloidogenic pathway on exposure to conditioned medium and in the presence of pro-inflammatory mediators.

Keywords: Amyloid-β, amyloid-β protein precursor, \textit{Porphyromonas gingivalis} conditioned medium
INTRODUCTION

Periodontal disease is one of the most common diseases worldwide, affecting up to 50% of the global population [1]. This oral inflammatory disorder involves destruction of the soft and hard tissues which support teeth including gingivae, periodontal ligament, and alveolar bone. The chronic inflammation is a result of poor oral hygiene and the presence of bacterial infection from supra and subgingival microbiota, whereby Porphyromonas gingivalis has been identified as a keystone pathogen [2, 3]. P. gingivalis is a Gram-negative bacterium which has been extensively studied as one of the main etiological factors in periodontal disease due to its ability to produce several virulence factors and extracellular proteases such as lipopolysaccharides, fimbriae, and gingipains which can lead to the destruction of the tooth supporting structures and eventual tooth loss [4]. P. gingivalis has also been implicated in the instigation of inflammatory mediator (cytokines) release locally, which may lead to systemic spread via circulating blood [5, 6]. Hence, P. gingivalis attains greater significance not only in periodontitis but also as an initiator for pro-inflammatory cytokines (IL-1β, IL-6, and others) [7], which has been shown to contribute to the development of multiple systemic diseases including cardiovascular disease, hyperglycemia, and insulin resistance [8–14]. Periodontitis is a chronic condition, and its effective management requires frequent chairside periodontal therapy with patient’s adherence to oral hygiene and professional compliance.

Alzheimer’s disease (AD) is the most prevalent subtype of dementia comprising 60 to 80% of all dementia cases [15]. AD is a neurodegenerative disorder that is characterised by the clinical presentation and the two main neuropsychological lesions: neurofibrillary tangles (NFTs) and amyloid-β (Aβ) plaques [16]. Advancing age and inheritance of the Apolipoprotein E, allele 4 (APOE e4) susceptibility gene [17, 18] are widely recognised as risk factors contributing to the development of AD. An indirect effect of inheriting the APOE e4 gene variant with respect to patients with periodontal disease is, considered to be, an increased susceptibility of the host to microbial infections [19–21]. This genotype has also been linked to increased inflammatory burden in terms of cytokines (systemic circulation and in the brain) in response to bacterial LPS [21–23], and further increase the risk for an individual to both periodontitis, and AD [24]. Previous studies have demonstrated that oral infections with P. gingivalis alone or introduction of its lipopolysaccharide (LPS), can lead to the development of key AD neuropathological hallmark lesions [25–30]. In addition, inflammatory markers and signalling pathways pertinent to impaired learning and spatial memory [25–28], were also observed in the periodontitis-AD infection mice models [29–31].

While the efforts to elucidate AβPP amyloidogenic pathway mechanisms that release Aβ under the influence of P. gingivalis infection in vivo are still in progress, the present study aimed to investigate, in vitro effects of P. gingivalis (FDC 381) conditioned medium on the amyloidogenic processing of AβPP in the wild-type SH-SY5Y cell line. To our knowledge, previous studies have utilized P. gingivalis infection for in-situ release of these virulence factors, which mainly contain proteinases such as gingipains, LPS, outer membrane vesicles, fimbriae, short chain fatty acids (butyric acid and propionic acids), and bacterial DNA [32]. Since gingipains is the major constituent of the conditioned medium, our hypothesis is that it is the gingipain enzymes from the crude conditioned medium that may be responsible for AβPP cleavage. This study used the non-differentiated SH-SY5Y cell line as an in vitro model of neurodegeneration in line with previous publications [33] for drug discovery and for AβPP processing [34]. These two studies motivated us to choose the SH-SY5Y cells [34], over modified in vitro cell lines like “SH-SY5Y.APP695” cells [34], which in our hands also demonstrated two phenotypes.

MATERIALS AND METHODS

P. gingivalis conditioned medium as a source of crude virulence factors

P. gingivalis (ATCC strain FDC 381) was cultured under anaerobic conditions to density of 5 × 10⁹ per mL in Tryptone soya broth (VWR) supplemented with hemin (5 μg/mL final concentration, Sigma-Aldrich UK), and menadione (1 μg/mL final concentration) by a collaborator and co-author (SC) while based at the University of Florida, USA. The conditioned media containing crude virulence factors alongside the sterile growth medium Tryptone soya broth or TSB (as control) were received frozen on dry ice at the University of Central Lancashire and were kept at –80°C before use under specified cell culture conditions.
In vitro cell culture

The human neuroblastoma SH-SY5Y, CRL-2266™ cell line was obtained from the American Type Culture Collection (ATCC) (https://www.atcc.org/products/SH-SY5Y CR-2266™). The cell line was cultured in Dulbecco’s modified Eagle’s medium (DMEM, Lonza code BE12-604F) supplemented with 5% fetal bovine serum (FBS). Test cells at 80% confluence were challenged for 48 h with/recombinant cytokine(s) IL-1β at 10 ng/ml, (Gibco, Thermo Fisher Scientific, UK); TNF-α at 10 ng/ml and IL-6 at 5 ng/ml, (Gibco, Thermo Fisher Scientific, UK) alone and combined with P. gingivalis virulence factors. The sterile microbiological growth (TSB) medium, used as a control, was diluted 1:5 in DMEM (University of Florida, USA). This dilution factor was determined by a prior in-house cytotoxicity assay, which demonstrated P. gingivalis conditioned medium containing virulence factors diluted 1:5 was non-toxic to this non-differentiated neuroblastoma cell line in culture. The SH-SY5Y cells were grown in flasks, incubated at 37°C in a humidified atmosphere of 5% CO2, 95% air.

Cell lysate preparation

Following 48-h treatments, the supernatants from the SH-SY5Y cells were collected into sterile 15 mL Falcon tubes. They were centrifuged (Sigma3-16K, Sigma-Aldrich, UK) for 5 min at 3000 rpm to remove cell debris, and stored at −80°C. The remaining adhered cells in the flasks were washed twice with 5 mL phosphate buffered saline (PBS), detached, and stored at –80°C until needed for western blotting (AβPP cleavage products).

Protein assay

Coomassie Blue Protein Assay (Sigma-Aldrich, UK) was performed to determine total protein concentration as described fully elsewhere [13].

Western blot analysis of cell lysates

All lysates from the SH-SY5Y cell line (P. gingivalis virulence factors, cytokines, and combined P. gingivalis virulence factors with cytokines) were separated by SDS-PAGE on precast 12% mini-protein TGB stain-free linear gels (BioRad Laboratories, USA). Protein ladder, (PageRuler Plus, 26619, from Thermo Scientific) was loaded in the first well of each gel. All samples (10 μg) of total protein extracted from Laemmli reducing sample buffer containing 0.3% mercaptoethanol (Alfa Aesar) was electroblotted onto polyvinylidene difluoride (PVDF) membranes, as previously described by Poole et al. [13]. The membranes were incubated overnight in rabbit anti-AβPP C-terminal (cat no A8717) antibody diluted 1/4000 and rabbit anti-AβPP N-terminal (cat no A8967) diluted 1/1000, both from Sigma Aldrich UK, and mouse anti-Aβ (clone 6E10) from BioLegend was diluted 1/1000 in PBS/5% milk on a rotary device at 4°C. Chemiluminescent substrate (SuperSignal West Pico, ThermoFisher Scientific, UK) was prepared and applied to the membranes according to the manufacturer’s instructions. Specific protein signal from the membranes was visualized using a ChemicDoc® (Bio-Rad, UK) and images captured with Image Lab® Software Version 3.0.1. India ink (Windsor & Newton) was used to stain the membrane to determine the amount of protein transferred onto the membrane(s) as a loading control. Briefly the PVDF membrane was washed free of the chemiluminescent substrate in PBS (3 changes for 1 min each while agitating the membrane in a plastic container). Neat India ink (100 μL) in 50 mL of PBS was mixed and the membrane was transferred in it while shaking on a rotary platform. Within 3–5 min, the bands appeared on the membrane where the protein had electrophoresed. The membrane was gently washed free of the ink in distilled water (3 changes for 1 min each). The membrane was allowed to air
dry at room temperature for at least 1 h and preferably overnight. Densitometry was carried out on the bands (in triplicate blots) using the Image J software, and the resulting data was normalized to the loading control.

Transmission electron microscopy detection of Aβ fibrils

For negative staining, all supernatants were dispensed as 50 µL droplets onto Nescofilm (Bando Chemical Industries Ltd. Kobe, Japan) in a humidified chamber. Formvar/carbon coated nickel grids (400 mesh) were floated, film side down, on droplets of each supernatant for 20 min, transferred to 1% glutaraldehyde in PBS for 10 min, and washed by placing on droplets of PBS (3 x 1 min) and reverse osmosis-purified water for 6 x 1 min. Grids were then transferred to 2% uranium acetate for 10 min, lifted off with fine forceps, excess stain solution was drained with Whatman 50 filter paper and grids allowed to air dry before examination in a Philips CM12 TEM (FEI UK Ltd) at 80 kV. Images were captured with a Megaview III camera and AnalySIS software (Soft Imaging System GmbH, Germany). Aβ fibrils, prepared from a commercial peptide C99 (Severn Biotech, UK) that was reconstituted to 1 mg/mL in Ringer’s buffer acted as a positive control.

Statistical analysis

The data was evaluated using the Statistical Package for the Social Sciences (SPSS). The data was non-parametric, and the Mann-Whitney U test was used to determine the differences between two independent groups which were SH-SY5Y untreated (TSB) versus Pg381; TNF-α versus Pg381 + IL-1β, and Pg381 + TNF-α. The low molecular bands correspond to the AβPP C99 fragment in the Pg381 treated group, IL-6 and significantly more intensely with Pg381 + IL-1β and Pg381 + TNF-α. The AβPP C83 band is in lanes TNF-α and with Pg381 + IL-1β, Pg381 + IL-6, and Pg381 + TNF-α.

RESULTS

Western blot: Rabbit anti-AβPP C-terminal antibody

Following immunoblotting of the cell lysates, several high molecular weight bands in the region of 100-80 kDa corresponding to AβPP695, AβPP751, and AβPP770 (not quantified) were observed (Fig. 1A) in lanes control or TSB, Pg381, IL-6, Pg381 + IL-1β, and Pg381 + TNF-α. The low molecular bands corresponding to the AβPP C99 dimerized fragment were observed in the Pg381 treated group, IL-6 and significantly more intensely with Pg381 + IL-1β and Pg381 + TNF-α. The dimerized band corresponding to the AβPP C83 fragment was observed in groups with cells treated with TNF-α alone and with Pg381 + IL-1β, Pg381 + IL-6, and Pg381 + TNF-α.

C99 dimer bands densitometry

Statistically the results for the C99 bands (Fig. 1B), were highly significant across (TSB) versus Pg381; TNF-α versus Pg381 + TNF-α; IL-1β versus Pg381 + IL-1β; and IL-6 versus Pg381 + IL-6 treated groups. Aβ40 and Aβ42 levels were also evaluated statistically as per above groups and as relative Aβ40 and Aβ42 across all test conditions versus TSB control. A statistical probability (p value), less than or equal to ≤ 0.05 was considered significant.

Western blot: Rabbit anti-AβPP N-terminal antibody

The cell lysates immunoblotted with the anti-AβPP N-terminal antibody only weakly detected the
Fig. 1B. Densitometric analysis of the cell lysate immunoblotted with anti-AβPP C-terminal antibody C99. All error bars represent standard error of mean. Figure 1B: Statistical analysis of the results for the C99 bands (B): p values were highly significant across (TSB) versus Pg381 (p = 0.0001); TNF-α versus Pg381 + TNF-α (p = 0.00003); IL-1β versus Pg381 + IL-1β (p = 0.0000001); and IL-6 versus Pg381 + IL-6 (p = 0.00003).

Fig. 1C. Densitometrical analysis of the cell lysate immunoblotted with anti-AβPP C-terminal antibody. Statistical analysis of the results for the AβPP C83 fragment (Fig. 1 C). p values were not significant across (TSB) versus Pg381 (p = 0.3); TNF-α versus Pg381 + TNF-α (p = 0.2); but are very significant for IL-1β versus Pg381 + IL-1β (p = 0.003); and highly significant for IL-6 versus Pg381 + IL-6 (p = 0.00002).

full AβPP bands at the 1/4000 dilution tested and other bands which were considered non-specific.

Western blot: Mouse anti-Aβ (clone 6e10) antibody

The anti-Aβ antibody apart from detecting the high molecular weight AβPP, also detected a range of AβPP cleavage fragments and above all detected the Aβ40 and Aβ42 bands as compared with the standard, reconstituted Aβ42 peptide (Fig. 2A). The Aβ40 and Aβ42 bands were statistically significant when Aβ40 and Aβ42 was pooled across test samples and compared to the untreated (TSB) for both Aβ species.

Aβ40 densitometry

Statistically the results for the Aβ40 band (Fig. 2B), were significant across (TSB) versus Pg381 (p = 0.013); TNF-α versus Pg381 + TNF-α (p = 0.0007). IL-1β was highly significant ver-
**Fig. 2A.** Western blot image from mouse anti-Aβ antibody; and related densitometric analysis of Aβ40 and Aβ42 bands (B, Aβ40; C, Aβ42) and when data was pooled for the relative abundance of Aβ. The anti-Aβ antibody apart from detecting the full AβPP and variable length cleavage fragments were also detected in addition to Aβ40 and Aβ42.

sus Pg381 + IL-1β (p = 0.0006); and IL-6 versus Pg381 + IL-6 (p = 0.006).

**Aβ42 densitometry**

Statistically the results for the Aβ42 band (Fig. 2C), were highly significant across control (TSB) over to Pg381 (p = 0.0006); TNF-α versus Pg381 + TNF-α (p = 0.0001). IL-1β was significant over Pg381 + IL-1β (p = 0.001); and IL-6 was significant over Pg381 + IL-6 (p = 0.03).

**Aβ40 and Aβ42 relative abundance densitometry**

When the relative abundance of both species Aβ40 and Aβ42 was statistically evaluated, the results for Aβ40 and Aβ42 across control (TSB) were highly significant over TSB versus all treatment groups for Aβ40 (p = 0.0007); and for Aβ42 TSB versus all treatment groups (p = 0.00008) (Fig. 2D).

The ratio of the pooled Aβ40 and Aβ42 from the densitometry values from intracellular stores was around 1:2 for both species compared with the control (TSB).

**Transmission electron microscopy for detection of Aβ fibril formation in supernatants**

The test supernatants collected from the treatment of cells with *P. gingivalis* conditioned medium with or without cytokines demonstrated the presence of fibrils. The supernatant from SH-SY5Y treated with *P. gingivalis* 381 conditioned medium consistently demonstrated insoluble fibrils (Fig. 3A boxed area and B arrows) that were interpreted as being Aβ fibrils based on comparison with the Aβ42 peptide included as a positive control (Fig. 3C).

**DISCUSSION**

The aim of the present study was to understand how the periodontal disease keystone pathogen *P. gingivalis* endo/exotoxins contribute to the amyloidogenic processing of AβPP and Aβ release because periodontitis is prevalent in individuals with poor oral hygiene and a high dental plaque index, which represents a risk factor for developing AD later in
Fig. 2C. Aβ42 densitometry. Statistically the results for the Aβ42 band (C), were across control (TSB) significant over to Pg381 (p = 0.0006); TNF-α versus Pg381 + TNF-α (p = 0.0001). IL-1β was significant over Pg381 + IL-1β (p = 0.001); and IL-6 was significant over Pg381 + IL-6 (p = 0.03).

Fig. 2D. Aβ40 and Aβ42 relative abundance densitometry. When relative abundance of both species Aβ40 and Aβ42 was statistically evaluated, the results for Aβ40 and Aβ42 (Fig. 2D), across control (TSB). TSB versus all treatment groups for Aβ40 (p = 0.0007); were highly significant, and for Aβ42 TSB versus all treatment groups were also significant (p = 0.00008). All error bars represent standard error of mean.

In the absence of an ideal immortalized neuronal cell line model and based on the knowledge that the non-differentiated SH-SY5Y cell line had been tested for AβPP processing via amyloidogenic pathway [34], we adopted this as a model cell line to elucidate the effect of bacterial factors on the AβPP processing to Aβ. In the present study, SH-SY5Y cells were tested without employing the use of chemical stimuli (retinoic acid, tumor promoter 12-O-tetradecanoyl-phorbol-13-acetate, or brain-derived neurotrophic factor) as reported elsewhere [41] which enable a single phenotype shift toward neuronal cells because prior knowledge of any potential aberrant effect on cellular pathophysiology of the chemical stimuli on AβPP processing were poorly understood. Since the AβPP gene is expressed...
by all CNS cells due to its “housekeeping gene” function, the AβPP processing in this bi-phenotypic cell line can at least be attributed to a neuronal-like cell phenotype as the origins of the cell line after all are from a neuroblastoma. Immunoblotting with three different antibodies for detecting full-length AβPP of variable isotypes, demonstrated several bands of variable molecular weight sizes, some corresponding to the full-length AβPP and others representing its fragmented moieties including Aβ40 and Aβ42.

As inflammation is usually associated with an infection, we combined the virulence factors of P. gingivalis with the three most common proinflammatory cytokines in this in vitro study and demonstrated the risk was heightened for liberation of Aβ40 and Aβ42 in the presence of either the conditioned medium or TNF-α, IL-1β, and IL-6 and upon their combination. The putative C99 dimerized fragment was decided upon as the molecular weight of this band suggested it to a dimerized state. Next, we searched for the literature to support this view and in this context, literature on the crystal structure of AβPP supported the reasoning for this fragment existing in its dimerized form due to its N-terminal having growth factor-like domain [42, 43] and is prone to dimerization. Further cleavage of AβPP became apparent with the 4 and 3 kDa Aβ bands detected by western blotting as confirmed by the standard used (Aβ peptide) for these AβPP metabolites [44]. Statistically significant Aβ40 was released by the combination of Pg381 + TNF-α and Pg381 + IL-6. Statistically significant Aβ42 was released by the combination of Pg381 + TNF-α treatment only. These observations are of significance as understanding the amyloidogenic processing of AβPP via infection is important as Aβ moiety that forms the hallmark protein of AD plaques could potentially be a source of recurrent infections during life and AD.

Wu et al. [25] demonstrated the intracellular Aβ and this has led us to explore Aβ40 and Aβ42 levels using more sensitive assays on the SH-SY5Y cell lysates and supernatants. It has been suggested that the mechanism of Aβ cleavage in the wild-type AβPP (not mutated) is mediated by cathepsin B and potentially by gingipains (P. gingivalis protease) [45]. It is not entirely clear where the cleavage sites of AβPP mediated by gingipains lie in the AβPP protein, but the implication is around the β- and γ-secretase sites for Aβ40 and Aβ42 liberation. The present study is suggestive of enhanced AβPP C99 fragmentation by the P. gingivalis conditioned medium on SH-SY5Y cells. Therefore, the AβPP cleavage by gingipains at the β- and γ-secretase sites is plausible. The C83 band appears responsive to the inflammatory mediators, especially TNF-α, IL-1β, and IL-6 in combination with the P. gingivalis conditioned medium suggesting that the α secretase is also active under these experimental conditions. Alternatively, Aβ40 and Aβ42 release observed in the SH-SY5Y cell line could simply be a catabolic process, in which case it agrees with Haas et al. [44], who also demonstrated these two Aβ species in their cell lines (not SH-SY5Y) in vitro.

Further studies to clarify the role of AβPP cleavage by gingipains are needed because of the plethora of publications, which provide evidence towards the oral pathogen P. gingivalis being implicated in the initiation and/or progression AD. The present study builds on the previous in vitro and in vivo studies [25, 29, 44, 46] and suggests the Aβ peptide release as an antimicrobial peptide innate immune protein [46]. This links in with the brains limited ability to clear microbial pathogens because of its reliance on the innate immune inflammatory responses, which by becoming chronic (due to genetic defects) result in enhancing neurodegeneration associated with AD [47, 48].
Evidence suggests that low levels of endogenous Aβ seen in the healthy brain is essential to enhance hippocampal long-term potentiation and synaptic plasticity, ultimately boosting memory formation [49]. This helps to explain why the antibody-based therapies developed for AD patients to mop up Aβ have not resulted in improved memory [50] and alternative therapies inclusive of bacterial aspects should now be investigated [51].

In the present study, we also show Aβ fiber formation with a similar fiber appearance to those reported by Kumar et al. [46]. The present study suggests that the presence of virulence factors or the live P. gingivalis bacterium itself can contribute to AβPP processing and enhance the release of Aβ40 in combination with IL-6 and Aβ42 release with TNF-α via the amyloidogenic pathway in vitro. It is, therefore, plausible to suggest that P. gingivalis virulence factors acting as antigens of the immune system can trigger the release of Aβ that eventually deposits as the extracellular plaques seen in AD autopsy brains where P. gingivalis and its virulence factors and pro-inflammatory mediators have been detected [13, 14, 52, 53].

Limitations of the study

We have used the wild-type SH-SY5Y in this study. This cell line is a neuroblastoma derived, non-differentiated immortalized cell line representing a mixed phenotype with predominantly cancer cells. Therefore, the translational value of the results presented here may vary and not fully simulate the results of other fully differentiated cell types.

Conclusions

The SH-SY5Y cell line when challenged alone with P. gingivalis virulence factors and/or combined with TNF-α and IL-1β enhances the AβPP cleavage. The release of C99 fragment appears to be influenced by P. gingivalis virulence factors, especially gingipains acting on the β- and γ-secretase sites, but further work needs to be carried out to definitively confirm this observation. The present study shows that both inflammation and infection can contribute to excessive release of Aβ40 and Aβ42.
