(Dated: November 3, 2018)

The symmetry energy for nuclear matter and its relation to the neutron skin in finite nuclei is discussed. The symmetry energy as a function of density obtained in a self-consistent Green function approach is presented and compared to the results of other recent theoretical approaches. A partial explanation of the linear relation between the symmetry energy and the neutron skin is proposed. The potential of several experimental methods to extract the neutron skin is examined.

I. INTRODUCTION

The nuclear symmetry energy plays a central role in a variety of nuclear phenomena. It determines to a large extent the equation of state (EoS) and the proton fraction of neutron stars, the neutron skin in heavy nuclei, etc. Its value at nuclear saturation density, the equation of state (EoS) and the proton fraction of neutron stars, the neutron skin in heavy nuclei, it enters as a substantially larger variation.

Wide range of predictions for the symmetry energy, 24-40 MeV. However, predictions for its density dependence show of relativistic mean field (RMF) models (which fit observables for isospin symmetric nuclei well) lead to a relatively 30 MeV, seems reasonably well established, both empirically as well as theoretically; still different parametrizations do not seem to agree well.

The many-body approximations employed. For instance the results of lowest order BHF and variational calculations [11]. On the other hand the symmetry energy and in particular its density dependence can vary substantially with has been shown that the calculated symmetry energy is quite insensitive to details of modern realistic NN interactions [7]. Furthermore a precise

II. THE SYMMETRY ENERGY IN NUCLEAR MATTER

The symmetry energy $S(\rho)$ is defined in terms of a Taylor series expansion of the energy per particle for nuclear matter in terms of the asymmetry $\alpha = (N - Z)/A$ (or equivalently the proton fraction $x = Z/A$),

\[ E(\rho, \alpha) = E(\rho, 0) + S(\rho)\alpha^2 + O(\alpha^4) + \ldots \]  

(1)
It has been shown that deviations from the parabolic law in Eq. (1), i.e. terms in $\alpha^4$, are quite small. Near the saturation density $\rho_0$ the energy of isospin-symmetric matter $E(\rho,0)$ and the symmetry energy can be expanded as

$$E(\rho,0) = E_0 + \frac{K}{18\rho_0^2}(\rho - \rho_0)^2 + \ldots$$

and

$$S(\rho) = \frac{1}{2} \frac{\partial^2 E(\rho,\alpha)}{\partial \alpha^2} |_{\alpha=0} = a_4 + \frac{p_0}{\rho_0}(\rho - \rho_0) + \frac{\Delta K}{18\rho_0^2}(\rho - \rho_0)^2 + \ldots$$

The parameter $a_4$ is the symmetry energy at equilibrium and the slope parameter $p_0$ governs the density dependence.

The relevance of the nuclear matter results in part depends on the question whether there is a surface contribution to the symmetry energy for finite nuclei. In ref. it was found that the latter is of minor importance, which has also been confirmed in [2].

### A. Self-consistent Green function and Brueckner approach

In this section we describe the calculation of the symmetry energy in the SCGF approach. Since the latter can be considered as a generalization of the lowest order Brueckner-Hartree-Fock (BHF) method we start with a brief discussion of the symmetry energy in the latter case.

#### 1. Symmetry energy in BHF

In the Brueckner-Hartree-Fock approximation, the Brueckner-Bethe-Goldstone (BBG) hole-line expansion is truncated at the two hole-line level. The short-range NN repulsion is treated by a resummation of the particle-particle ladder diagrams into an effective interaction or $G$-matrix. Self-consistency is required at the level of the BHF single-particle spectrum $\epsilon_B(\mathbf{k})$,

$$\epsilon_{BHF}(k) = \frac{k^2}{2m} + \sum_{k' < k_F} \text{Re} < kk' | G(\omega = \epsilon_{BHF}(k) + \epsilon_{BHF}(k')) | kk' > .$$

In the standard choice BHF the self-consistency requirement is restricted to hole states ($k < k_F$) only, while the free spectrum is kept for particle states $k > k_F$. The resulting gap in the s.p. spectrum at $k = k_F$ is avoided in the continuous-choice BHF (ccBHF), where Eq. (4) is used for both hole and particle states. The continuous choice for the s.p. spectrum is closer in spirit to many-body Green’s function perturbation theory. Moreover, recent results indicate that the contribution of higher-order terms in the hole-line expansion is considerably smaller if the continuous choice is used.

The BHF energy per nucleon can be easily evaluated for both symmetric nuclear matter (SNM) and pure neutron matter (PNM) using the energy sum-rule,

$$\frac{E}{A} = \frac{d}{\rho} \int \frac{d^3k}{(2\pi)^3} \left( \frac{k^2}{2m} + \epsilon_{BHF}(k) \right) \theta(k_F - k),$$

where $\rho = \frac{4\pi^2}{3} \rho$ is the density and $d$ is the isospin degeneracy ($d = 1(2)$ for PNM (SNM)). The symmetry energy $S(\rho)$ is obtained as the difference between PNM and SNM energies for the same density.

We first performed ccBHF calculations with the Reid93 interaction, including partial waves with $J < 4$ in the calculation of the G-matrix. The results are presented in Fig. where the symmetry energy $S$ is decomposed into various contributions as suggested in ref. and shown as a function of nucleon density $\rho$. The contribution $S_{\text{kin}}$ of the kinetic energy to the BHF symmetry energy is given by the free Fermi-gas expression [44]

$$S_{\text{kin}} = E_{\text{kin},PNM} - E_{\text{kin},SNM} = \frac{3}{10m} (3\pi^2)^\frac{3}{2} \rho^{\frac{5}{2}} \left( 1 - \frac{1}{2\pi} \right),$$

and it determines to a large extent the density dependence of $S$. In Fig. we also show the symmetry potential $S_{\text{pot}} = S - S_{\text{kin}}$, which is much flatter, and the contributions to $S_{\text{pot}}$ from both the isoscalar ($T = 0$) and isovector
FIG. 1: The symmetry energy $S$ (full line) and the contributions to $S$ from the kinetic (dash-dotted line) and potential energy (dashed line), calculated within a ccBHF scheme and using the Reid93 interaction. Also shown (dotted lines) are the $T=0$ and $T=1$ components of the potential energy contribution.

$(T=1)$ components of the interaction. Over the considered density range $S_{\text{pot}}$ is dominated by the positive $T=0$ part. The $T=0$ partial waves, containing the tensor force in the $^{3}S_{1}-^{3}D_{1}$ channel which gives a major contribution to the potential energy in SNM, do not contribute to the PNM energy. The $T=0$ contribution peaks at $\rho \approx 0.3$ fm$^{-3}$. The decrease of this contribution at higher densities is compensated by the increase of the $T=1$ potential energy, with as a net result a much weaker density-dependence of the total potential energy. (It should be noted that inclusion of a three-nucleon interaction in general leads to a substantial increase for the slope parameter $p_{0}$ [13].)

2. Symmetry energy in SCGF approach

In recent years several groups have considered the replacement of the BBG hole-line expansion with self-consistent Green’s function (SCGF) theory [19, 20, 21, 22, 23, 24]. In [23, 24] the binding energy for SNM was calculated within the SCGF framework and using the Reid93 potential. In the present paper we have extended these calculations to PNM and calculated the corresponding symmetry energy. Details of a technical nature can be found in [23].

A SCGF calculation differs in two important ways from a BHF- calculation. Firstly, within SCGF particles and holes are treated on an equal footing, whereas in BHF only intermediate particle ($k > k_{F}$) states are included in the ladder diagrams. This aspect ensures thermodynamic consistency, e.g. the Fermi energy or chemical potential of the nucleons equals the binding energy at saturation (i.e., it fulfills the Hugenholz-van Hove theorem). In the low-density limit BHF and SCGF coincide. As the density increases the phase space for hole-hole propagation is no longer negligible, and this leads to an important repulsive effect on the total energy. Secondly, the SCGF generates realistic spectral functions, which are used to evaluate the effective interaction and the corresponding nucleon self-energy. The spectral functions include a depletion of the quasi-particle peak and the appearance of single-particle strength at large values of energy and momentum, in agreement with experimental information from $(e,e')p$ reactions. This is in contrast with the BHF approach where all s.p. strength is concentrated at the BHF-energy as determined from Eq. 4.

In a SCGF approach the particle states ($k > k_{F}$), which are absent in the BHF energy sum rule of Eq. 5, do
contribute according to the energy sum rule

$$E/A = \frac{d}{\rho} \int \frac{d^3k}{(2\pi)^3} \int_{-\infty}^{\infty} d\omega \left( \frac{k^2}{2m} + \omega \right) S_h(k, \omega),$$

expressed in terms of the nucleon spectral function $S_h(k, \omega)$.

The results for the ccBHF and SCGF calculations for both SNM and PNM are compared in the left and central panels of Fig. 2 for the Reid93 interaction. The inclusion of high-momentum nucleons leads roughly to a doubling of the kinetic and potential energy in SNM, as compared to BHF. As seen in Fig. 2, the net result for the total energy of SNM is a repulsive effect, increasing with density\(^2\). This leads to a stiffer equation of state, and a shift of the SNM saturation density towards lower densities. The above effects are dominated by the tensor force (the isoscalar \(^3S_1 - ^3D_1\) partial wave). Consequently, the effects are much smaller in PNM.

The corresponding symmetry energy, shown in the right panel of Fig. 2, is dominated by the shift in the total energy for SNM, and lies below the ccBHF symmetry energy in the entire density-range. At $\rho_0 = 0.16 \text{ fm}^{-3}$ the symmetry energy parameter $a_4$ is reduced from 28.9 MeV to 24.9 MeV, while the slope $p_0$ remains almost the same (from 2.11 MeVfm\(^{-3}\) to 1.99 MeVfm\(^{-3}\)).

B. Comparison of symmetry energy in other approaches

1. Calculations with realistic NN forces

Engvik et al.\(^1\) have performed lowest-order Brueckner-Hartree-Fock calculations in SNM and PNM for all “modern” potentials (CD-Bonn, Argonne v18, Reid93, Nijmegen I and II), which fit the Nijmegen NN scattering database with high accuracy. They concluded that for small and normal densities the symmetry energy is largely independent of the interaction used, e.g. at $\rho_0$ the values of $S$ vary around an average value of $a_4=29.83$ MeV by about 1 MeV. At larger densities the spread becomes larger; however, the symmetry energy keeps increasing with density, in contrast to some of the older potentials like Argonne v14 and the original Reid interaction (Reid68) for which $S(\rho)$ tended to saturate at densities larger than $\rho = 0.4$ fm\(^{-3}\). Some insight into the microscopic origin of the symmetry potential was obtained by Zuo et al.\(^2\) who decomposed the symmetry energy into contributions from...
TABLE I: Results for the symmetry energy parameters $a_4$ and $p_0$ from the variational calculations of Refs.\cite{17,18} using the Argonne and Urbana NN potentials, in combination with Urbana models for the three-nucleon interaction. The last column includes a relativistic boost correction $\delta v$ and the adjusted UIX* three-nucleon interaction.

|        | Av14 | Av14+UVIII | Uv14 | Uv14+UVIII | Av18 | Av18+UIX | Av18+$\delta v$+UIX* |
|--------|------|------------|------|------------|------|----------|----------------------|
| $a_4$  [MeV] | 24.90 | 27.49      | 26.39 | 28.76      | 26.92| 29.23    | 30.1                 |
| $p_0$  [MeV fm$^{-3}$] | 2.02  | 2.71       | 2.38 | 3.04        | 1.95 | 2.34     | 2.95                 |

kinetic and potential energy. The BHF calculations in \cite{12} used the Argonne v14 and the separable Paris interaction. In Fig.1 we showed that the use of the modern Reid93 potential leads to essentially the same conclusions.

Detailed studies for SNM and PNM using variational chain summation techniques were performed by Wiringa et al. \cite{17} for the Argonne Av14 and Urbana Uv14 NN interaction, in combination with the Urbana UVIII three-nucleon interaction (TNI), and by Akmal et al. \cite{18} for the modern Av18 NN potential in combination with the UIX-TNI. Results for $a_4$ and $p_0$, extracted from \cite{17} and \cite{18}, are shown in Table I. The inclusion of TNI stiffens the EoS for both SNM and PNM, and increases considerably the value of the symmetry energy $a_4$ and its slope $p_0$ at the empirical density $\rho_0$. The effect of including a relativistic boost correction $\delta v$ (in combination with a refitted TNI) on the values of $a_4$ and $p_0$ is sizeable as well.

The symmetry energy has also been computed in the Dirac-Brueckner-Hartree-Fock (DBHF) approach \cite{25,26}. In relativistic approaches the symmetry energy generally is found to increase almost linearly with density, and more rapidly than in the non-relativistic case. This difference can be attributed to two effects. First the covariant kinetic energy which is inversely proportional to $\sqrt{k_F^2 + m^*}$ is larger because of the decreasing Dirac mass, $m^*$, with increasing density. Secondly the contribution from rho-exchange appears to be larger than in the non-relativistic case \cite{27}.

2. Mean-field approach using effective interactions

Since the Furnstahl relation has been verified mainly in terms of mean-field models we discuss some results obtained in these approaches, which in general are based upon a parameterized effective interaction.

Brown \cite{5} has investigated proton and neutron radii in terms of the non-relativistic Skyrme Hartree-Fock (SHF) model. First he noted that a certain combination of parameters in the SHF is not determined well by a fit to ground state binding energies, and that a wide range of predictions for the EoS for PNM is obtained. He also pointed out a direct correlation between the derivative of the neutron matter EoS (i.e., basically the symmetry energy coefficient $p_0$) and the neutron skin in $^{208}$Pb.

Covariant approaches are in general based upon either a covariant lagrangian with $\sigma$, $\omega$ and $\rho$ exchange (and possibly other mesons) \cite{8,27}, or on the use of contact interactions \cite{2}, solved as an energy density functional (EDF) in the Hartree-Fock approximation. Sets of model parameters are determined by fitting bound state properties of nuclei. Specifically the isovector degree of freedom is determined by the exchange of isovector mesons; in case of rho-meson exchange the (positive definite) contribution to $S$ is given by

$$a_4 = \frac{k_F^2}{6\sqrt{m^*} + k_F^*} + \frac{g_\rho^2}{8m^*_\rho^2} p_0,$$

and its potential energy contribution to $p_0$, which scales with that for $a_4$, is $\frac{g_\rho^2}{8m^*_\rho^2}$. Typical values obtained for $p_0$ are around 4-6 MeV fm$^{-3}$, and $a_4 \sim 30-36$ MeV, i.e. considerably larger than in non-relativistic approaches (a large part of the enhancement can be ascribed to the fact that the kinetic contribution is larger, because $m^* < m$). Recently in \cite{28,29} this approach was extended by inclusion of the isovector-scalar partner, $\delta$, of the isoscalar scalar $\sigma$-meson. Because of the presence of the Lorentz factor $m^* / E$ in the scalar potential contribution, $\sim \frac{g_\rho^2}{8m^*_\rho^2} \frac{m^*}{E}$, which decreases with increasing density its inclusion leads to an even larger net value for $p_0$ \cite{28,29}.

Since explicit pion exchange is usually not included in the mean field approaches it is difficult to make a meaningful comparison with microscopic ones. In fact it can be argued that in contrast to isoscalar properties the long-range pion exchange could play an essential role in determining the isovector properties \cite{2}.\[5\]
FIG. 3: Overview of several theoretical predictions for the symmetry energy \( S \): Brueckner-Hartree-Fock (continuous choice) with Reid93 potential (circles), self-consistent Green function theory with Reid93 potential (full line), variational calculation from [17] with Argonne Av14 potential (dashed line), Dirac-Brueckner-Hartree-Fock calculation from [25] (triangles), relativistic mean-field model from [28] (squares), effective field theory from [30] (dash-dotted line).

3. Effective field theory

Recently the density dependence of the symmetry energy has been computed in chiral perturbation effective field theory, described by pions plus one cutoff parameter, \( \Lambda \), to simulate the short distance behavior [30]. The nuclear matter calculations have been performed up to three-loop order; the resulting EoS is expressed as an expansion in powers of \( k_F \), and the value of \( \Lambda \approx 0.65 \text{ GeV} \) is adjusted to the empirical binding energy per nucleon. The value obtained in this approach for \( a_4 = 33 \text{ MeV} \) is in remarkable agreement with the empirical one; at higher densities \( (\rho > 0.2 \text{ fm}^{-3}) \) a downward bending is predicted. However, in its present form the validity of this approach is clearly confined to relatively small values of the Fermi momentum, i.e. rather low densities. It is interesting to note that there are relatively small (large) contributions to \( a_4 \) coming from one-pion exchange Fock diagram (three-loop diagrams with either two or three medium insertions).

4. Comparison

To summarize the present status in Fig. [IB4] various results of the approaches for \( S(\rho) \) discussed above are compared. As noted above one sees that the covariant models yield a much larger increase of \( S \) with the density than the non-relativistic approaches. The LOBHF leads to a higher value of \( S \) than both variational and the SCGF method which include more correlations; that the SCGF result is close to the variational approach may be fortuitous. Effects from three-body forces are not included.
III. RELATIONSHIP BETWEEN SYMMETRY ENERGY AND $\Delta R$

Brown and Furnstahl have pointed out that within the framework of mean-field models there exists an almost linear empirical correlation between theoretical predictions for both $a_{4}$ and its density dependence, $p_{0}$, and the neutron skin, $\Delta R = R_{n} - R_{p}$, in heavy nuclei. This observation suggests an intriguing relationship between a bulk property of infinite nuclear matter and a surface property of finite systems.

Here we wish to address this question from a different point of view, namely in the spirit of Landau-Migdal approach. Let us consider a simple mean-field model (see, e.g., [31]) with the Hamiltonian consisting of the single-particle mean field part $H_{0}$ and the residual particle-hole interaction $H_{p-h}$:

$$\hat{H} = \hat{H}_{0} + \hat{H}_{p-h}, \quad \hat{H}_{0} = \sum_{a} (T_{a} + U(x_{a})), \quad (9)$$

$$U(x) = U_{0}(x) + U_{1}(x) + U_{C}(x), \quad (10)$$

Here, the mean field potential $U(x)$ includes the phenomenological isoscalar part $U_{0}(x)$ along with the isovector $U_{1}(x)$ and the Coulomb $U_{C}(x)$ parts calculated consistently in the Hartree approximation; $U_{0}(x)$ and $U_{so}(x) = U_{so}(r)\hat{s} \cdot \hat{l}$ are the central and spin-orbit parts of the isoscalar mean field, respectively; $S_{pot}(r)$ is the symmetry potential (the potential part of the symmetry energy).

In the Landau-Migdal approach the effective isovector particle-hole interaction $\hat{H}_{p-h}$ is given by

$$\hat{H}_{ph} = \sum_{a>b} (F' + G' \hat{s}_{a} \hat{s}_{b}) \hat{T}_{a} \hat{T}_{b} \delta(\vec{r}_{a} - \vec{r}_{b}), \quad (11)$$

where $F'$ and $G'$ are the phenomenological Landau-Migdal parameters.

The model Hamiltonian $\hat{H}$ in Eq. (11) preserves isospin symmetry if the condition

$$[\hat{H}, \hat{T}^{(--)}] = \hat{U}^{(--)}_{C}, \quad (12)$$

is fulfilled, where $\hat{T}^{(--)} = \sum_{a} \hat{T}_{a}^{(--)}, \quad \hat{U}^{(--)}_{C} = \sum_{a} U_{C}(r_{a}) \hat{T}_{a}^{(--)}$. With the use of Eqs. (10), (11), (12) the condition eq. (12) in the RPA formalism leads to a selfconsistency relation between the symmetry potential and the Landau parameter $F'$:

$$S_{pot}(r) = 2F' n^{(-)}(r), \quad (13)$$

where $n^{(-)}(r) = n^{n}(r) - n^{p}(r)$ is the neutron excess density. Thus, in this model the depth of the symmetry potential is controlled by the Landau-Migdal parameter $F'$ (analogously to the role played by the parameter $g_{s}^{2}$ in relativistic mean field models).

$S_{pot}(r)$ is obtained from Eq. (13) by an iterative procedure; the resulting dependence of $\Delta R$ on the dimensionless parameter $f' = F'/(300 \text{ MeV fm}^{3})$ shown in fig. 4 indeed illustrates that $\Delta R$ depends almost linearly on $f'$. Then with the use of the Migdal relation [32] which relates symmetry energy and $f'$,

$$a_{4} = \frac{c_{F}}{3}(1 + 2f'), \quad (14)$$

a similar almost linear correlation between the symmetry energy, $a_{4}$, and the neutron skin is obtained.

To get more insight in the role of $f'$ we consider small variations $\delta F'$. Neglecting the variation of $n^{(-)}(r)$ with respect to $\delta F'$ one has a linear variation of the symmetry potential: $\delta S_{pot}(r) = 2\delta F' n^{(-)}(r)$. Then in first order perturbation theory, such a variation of $S_{pot}$ causes the following variation of the ground-state wave function

$$|\delta 0\rangle = \delta F' \sum_{s} \frac{(s|\hat{N}^{(-)}|0)}{E_{0} - E_{s}} |s\rangle, \quad (15)$$

with $s$ labeling the eigenstates of the nuclear Hamiltonian and a single-particle operator $\hat{N}^{(-)} = \sum_{a} n^{(-)}(r_{a}) \hat{T}_{a}^{(3)}$. Consequently the variation of the expectation value of the single-particle operator $\hat{V}^{(-)} = \sum_{a} r_{a}^{2} \hat{T}_{a}^{(3)}$ with $\langle 0|\hat{V}^{(-)}|0\rangle = NR_{n}^{2} - Z R_{p}^{2}$ can be written as

$$R_{p} \delta(\Delta R) = \delta F' \frac{2}{A} \sum_{s} \frac{\text{Re}(0|\hat{N}^{(-)}|s\rangle \langle s|\hat{V}^{(-)}|0\rangle)}{E_{0} - E_{s}}. \quad (16)$$
In practice the sum in Eq. (16) is exhausted mainly by the isovector monopole resonance of which the high excitation energy (about 24 MeV in $^{208}$Pb) justifies the perturbative consideration. We checked that Eq. (16) is able to reproduce directly calculated $\delta(\Delta R)$ shown in fig. 4 with the accuracy of about 10%. As a result a simple microscopic interpretation of the linear correlation between the neutron skin thickness and Landau parameter $F'$ is obtained.

IV. EXPERIMENTAL METHODS TO DETERMINE $\Delta R$

A variety of experimental approaches have been explored in the past to obtain information on $\Delta R$. To a certain extent all analysis contain a certain model dependence, which is difficult to estimate quantitatively. It is not our intention to present a full overview of existing methods for the special case of $^{208}$Pb. In particular the results obtained in the past from the analysis of elastic scattering of protons and neutrons have varied depending upon specifics of the analysis employed. At present the most accurate value comes from a recent detailed analysis of the elastic proton scattering reaction at $E = 0.5 – 1$ GeV [41], and of neutron and proton scattering at $E = 40 – 100$ MeV [42]. For details we refer to these papers. Here we restrict ourselves to a discussion of the some less well known methods that have the potential to provide more accurate information on the neutron skin in the future. In particular the excitation of isovector giant resonances through the restoring force contain information about the symmetry energy.

A. Isovector giant resonances

We begin with a brief overview of the study of excitation of isovector giant resonances. Sum rules for the latter contain direct information on $\Delta R$.

1. Giant Dipole Resonance (GDR)

In the past the excitation of the isovector giant dipole resonance (GDR) with isoscalar probes has been used to extract $\Delta R/R$ [34]. In the DWBA optical model analysis of the cross section the neutron and proton transition densities are needed as an input. In the Goldhaber-Teller picture

$$g_i(r) = -\kappa \frac{2N_i d\rho_i}{A} \frac{2N_i d\rho_i}{dr}$$

(17)

with $\kappa$ the oscillation amplitude and $(i = p, n)$. Assuming ground state neutron and proton distributions of the form $(x = (N - Z)/A)$

$$\rho_i(r) = \frac{1}{2} (1 \pm x \mp \gamma x) \rho(r - c(1 \pm \gamma x/3)).$$

(18)
While for $N = Z$ the transition density vanishes, for $N > Z$ the isovector transition density is finite
\[ \Delta g(r) = \kappa \gamma \frac{N - Z}{A} \left( \frac{d\rho}{dr} + \frac{c}{3} \frac{d^2\rho}{dr^2} \right), \]
where $\gamma$ is related to $\Delta R$, $\gamma = \frac{3A}{2(N-Z)} \Delta R/R_0$.

Excitation of the GDR by alpha particle scattering (isoscalar probe) the corresponding transition optical potential is given by
\[ \Delta U_{tr} = \kappa \gamma N - Z A \left( \frac{dU}{dr} + \frac{R_0 U_0^2}{3d^2r^2} \right), \quad (19) \]

By comparing the experimental cross section with the theoretical one (calculated as a function of the ratio $\Delta R/R$) the value of $\Delta R/R$ can be deduced.

It is difficult to make a quantitative estimate of the uncertainty in the result coming from the model dependence of the approach. In the analysis several assumptions must be made, such as the radial shape of the density oscillations and about the actual values of the optical model parameters.

2. Spin-dipole Giant Resonance

Recently it has been proposed to utilize the excitation of the spin-dipole resonance, excited in charge exchange reactions, to determine the neutron skin; in fact the method has been applied to obtain information on the variation of the neutron skin in the Sn isotopes with isotope number $^{35}$. For the relevant operator, $\sum \sigma_i \tau_i r_i Y_1(r_i)$, the summed $\Delta L = 1$ strength is
\[ S^(-) - S^+ = C(NR_n^2 - ZR_p^2). \quad (20) \]
Here $S^(-)$ and $S^+$ are the spin-dipole total strengths in $\beta^(-)$ and $\beta^+$ channels, respectively; $C$ is the factor depending on the definition of the spin-dipole operator (in the definition of Ref. [2] $C = 1/4 \pi$, we use here $C = 1$). Because $S^+$ could not be measured experimentally, the model-dependent energy-weighted sum rule was invoked in the analysis to eliminate $S^+$. Let put $S^+ = 0$ (that seems to be a very good approximation for $^{208}$Pb) and ask the question what experimental accuracy for $S^-$ is needed to determine the neutron skin to a given accuracy. With
\[ S^-(N-Z)R_p^2 + 2NR_p\Delta R \]
the ratio of the second term on the rhs to the first one in case of $^{208}$Pb is
\[ 2N\Delta R/((N-Z)R_p) \approx 5.7\Delta R/R_p. \]
Therefore, for $R_p = 5.5$ fm and $\Delta R = 0.2$ fm the second term is only 25% of the first one and one needs 3% accuracy in $S^-$ to determine $\Delta R$ with 10% accuracy. Because the SDR strength is spread out and probably has a considerable strength at low-energy the results for the $\Delta R$ can be only considered as qualitative with a relatively large uncertainty (of order 30-50%).

3. Isobaric analogue state

The dominant contribution to the energy weighted sum rule (EWSR) for Fermi excitations by the operator $T^-$ comes from the Coulomb mean field
\[ (EWSR)_F = \int U_C(r)n^-(r)d^3r. \quad (22) \]
The Coulomb mean field $U_C(r)$ resembles very much that of the uniformly charged sphere, being inside a nucleus a quadratic function: $U_C(r) = \frac{Ze^2}{2R_c}(3 - (r/R_c)^2)$, $r \leq R_c$. It turns out that if one extends such a quadratic dependence also to the outer region $r > R_c$ (instead of proportionality to $R_c/r$), it gives numerically just very small deviation in
\((EWSR)_F\) (less than 0.5\%, due to the fact, that the difference and its first derivative go to 0 at \(r = R_c\) and \(n^{-}(r)\) is exponentially decreasing at \(r > R_c\)). Using such an approximation, one gets:

\[
(EWSR)_F \approx (N - Z)\Delta C \left(1 - \frac{S^{(-)}}{3(N - Z)R_c^2}\right)
\]  

with \(\Delta C = \frac{3Ze^2}{2R_c}\), and \(S^{(-)}\) given in Eq. \(21\).

Since the IAS exhausts almost 100\% of the NEWSR and EWSR, one may hope to extract \(S^{(-)}\) from the IAS energy. However, the term depending on \(S^{(-)}\) contributes only about 20\% to \((EWSR)_F\), and as a result, the part of \(S^{(-)}\) depending on \(\Delta R\) contributes only about 4\% to \((EWSR)_F\) (in \(^{208}\text{Pb}\)). \(^4\)From the experimental side, the IAS energy can be determined with unprecedentedly high accuracy, better than 0.1\%. Also, from the experimentally known charge density distribution the Coulomb mean field \(U_C(r)\) can be calculated rather accurately, and hence one can determine the small difference between Eqs. \(22\) and \(23\). But at the level of 1\% accuracy several theoretical effects discarded in Eq. \(22\) come into play (see, e.g., \(36\)) which makes the reliability of such a method questionable. On the other hand in a forthcoming paper we will show that for an isotopic chain the excitation of the IAS can be used as a quantitative tool to obtain the variation of \(\Delta R\) with neutron number.

### B. Anti-protonic atoms

Recently neutron density distributions were deduced from anti-protonic atoms \(^{37}\). The basic method determines the ratio of neutron and proton distributions at large differences by means of a measurement of the annihilation products which indicates whether the antiproton was captured on a neutron or a proton. In the analysis two assumptions are made. First a best fit value for the ratio \(R_I\) of the imaginary parts of the free space \(\bar{p}p\) and \(\bar{n}n\) scattering lengths equal to unity is adopted. Second in order to reduce the density ratio at the annihilation side to a ratio of rms radii a two-parameter Fermi distribution is assumed. The model dependence introduced by this assumptions is difficult to judge. Since a large number of nuclei have been measured one may argue that the value of \(R_I\) is fixed empirically.

### C. Parity violating electron scattering

Recently it has been proposed to use the (parity violating) weak interaction to probe the neutron distribution. This is probably the least model dependent approach \(^{35}\). The weak potential between electron and a nucleus

\[
\tilde{V}(r) = V(r) + \gamma_5 A(r),
\]

where the axial potential \(A(r) = \frac{G_F}{2\sqrt{2}}\rho_W(r)\). The weak charge is mainly determined by neutrons

\[
\rho_W(r) = (1 - 4\sin^2\theta_W)\rho_p(r) - \rho_n(r),
\]

with \(\sin^2\theta_W \approx 0.23\). In a scattering experiment using polarised electrons one can determine the cross section asymmetry \(^{38}\) which comes from the interference between the \(A\) and \(V\) contributions. Using the measured neutron form factor at small finite value of \(Q^2\) and the existing information on the charge distribution one can uniquely extract the neutron skin. Some slight model dependence comes from the need to ascertain a certain radial dependence for the neutron density, to extract \(R_n\) from a finite \(Q^2\) form factor.

### V. DISCUSSION OF \(\Delta R\) FOR \(^{208}\text{PB}\) AND SOME IMPLICATIONS

In table \(\text{V}\) we present a summary of some recent results on \(\Delta R\) in \(^{208}\text{Pb}\). One sees that (with the exception of the analysis of proton and neutron pickup reactions in terms of mean field orbitals in \(^{31}\)) all recent results are consistent with \(\Delta R \sim 0.13 \pm 0.03\) fm. Therefore it appears that the data agree with the result of conventional Skyrme model approach but seem to disagree with the results of the RMF models considered in \(^2\). On the basis of the correlation plot between \(\Delta R\) and \(p_0\) shown in \(^2\) one would then conclude that a small value for \(p_0 \sim 2\text{MeV/fm}^3\) is preferred over larger values predicted in RNF approaches.

In several processes of physical interest knowledge of \(\Delta R\) plays a crucial role and in fact a more accurate value could lead to more stringent tests:
TABLE II: Summary of recent results for $\Delta R$ in $^{208}$Pb

| method                              | $\Delta R$ [fm] | error [fm] | ref   |
|-------------------------------------|-----------------|------------|-------|
| giant dipole resonance excitation   | 0.19            | 0.09       | [34, 40] |
| neutron/proton pickup               | 0.51            |            | [39]  |
| ($\vec{p}, \vec{p}'$) at 0.5-1.04 GeV | 0.097           | 0.014      | [41]  |
| nucleon scattering (40-200 MeV)     | 0.17            |            | [42]  |
| anti-protonic atoms                 | 0.15            | 0.02       | [37]  |
| parity violating electron scattering| planned         | 0.05       | [38]  |

(i) The pion polarization operator $\Pi[9]$ (the s-wave optical potential) in a heavy nucleus $\Pi(\omega, \rho_p, \rho_n) = -T^+(\omega)\rho - T^-(\omega)(\rho_n - \rho_p)$ has mainly an isovector character ($T^+(m_p) \sim 0$). Parameterizing the densities by Fermi shapes for the case of $^{208}$Pb the main nuclear model dependence in the analysis comes from the uncertainty in the value of $\Delta R$ multiplying $T^-$. 

(ii) Parity violation in atoms is dominated by $Z$-boson exchange between the electrons and the neutrons $^{133}$Cs $^{11}$. Taking the proton distribution as a reference there is a small so-called neutron skin (ns) correction to the parity transition, which is related to $\Delta R$ as $^{133}$Cs \cite{43} (independent of the electronic structure)

$$\frac{\delta E_{\text{pnc}}^{\text{NS}}}{E_{\text{pnc}}} = \frac{3}{4}(\alpha Z)^2\frac{\Delta R}{R_p}. \quad \text{(26)}$$

In $^{133}$Cs it amounts to a $\delta E/E \approx -(0.1 - 0.4)\%$ depending on whether the non-relativistic or relativistic estimates for $\Delta R$ are used $^{11}$. The corresponding uncertainty in the weak charge $Q_W$ is $-(0.2 - 0.8)\%$.

(iii) The pressure in neutron star matter can be expressed as in terms of the symmetry energy and its density dependence $^{11}$

$$P(\rho, x) = \rho_x^2 \frac{\partial E(\rho, x)}{\partial \rho} = \rho_x^2 [E'(\rho, 1/2) + S'(\rho)(1 - 2x^2) + ...]. \quad \text{(27)}$$

By using the beta equilibrium condition in a neutron star, $\mu_e = \mu_n - \mu_p = -\frac{\partial E(\rho, x)}{\partial x}$, and the result for the electron chemical potential, $\mu_e = 3/4\hbar c x(3\pi^2 x^2)^{1/3}$, one finds the proton fraction near saturation density, $\rho_0$, to be quite small, $x_0 \sim 0.04$. Hence the pressure at saturation density can be approximated as

$$P(\rho_0) = \rho_0(1 - 2x_0)(\rho_0 S'(\rho_0)(1 - 2x_0) + S(\rho_0)x_0) \sim \rho_0^2 S'(\rho_0). \quad \text{(28)}$$

At higher densities the proton fraction increases; this increase is more rapid in case of larger $p_0$ $^8$. While for the pressure at higher densities contributions from other nuclear quantities like compressibility will play a role in $^1$ it was argued that there is a correlation of the neutron star radius and the pressure which does not depend on the EoS at the highest densities. Numerically the correlation can be expressed in the form of a power law, $R_M \sim C(\rho, M)^{P(\rho)_{\text{MeVfm}^{-1}}^{0.25} \text{ km}}$, where $C(\rho = 1.5\rho_0, M = 1.4M_\text{solar}) \sim 7$. This shows that a determination of a neutron star radius would provide some constraint on the symmetry properties of nuclear matter.

VI. CONCLUSION

In this paper we have discussed the bulk symmetry energy, and compared various approaches to compute it as a function of density. Because the tensor interaction plays an important role the symmetry energy is sensitive to details of the treatment of the many-body correlations. It was shown that the self-consistent Green function approach in which more correlations are included than in lowest order BHF leads to a smaller value of the symmetry energy. The relatively large values for $p_0$ obtained in the relativistic mean field approach can be associated with an effective mass effect.

We showed that the phenomenological almost linear relationship between symmetry energy and neutron skin in finite nuclei observed in mean field calculations could be understood in terms the Landau-Migdal approach. Finally we compared several experimental tools of potential interest for the determination of the neutron skin.
