Abstract

After a brief presentation of the MACRO detector we discuss the data on atmospheric neutrinos and neutrino oscillations, on high energy ($E_\nu > 1$ GeV) neutrino astronomy, on indirect searches for WIMPs and low energy ($E_\nu \gtrsim 7$ MeV) stellar collapse neutrinos.

1 Introduction

MACRO is a multipurpose underground detector designed to search for rare events in the cosmic radiation. It was optimized to search for the supermassive magnetic monopoles (MMs) predicted by Grand Unified Theories (GUT) of the electroweak and strong interactions. MACRO performs measurements in areas of astrophysics, nuclear, particle and cosmic ray physics. In this paper we shall discuss atmospheric neutrinos and neutrino oscillations, high energy ($E_\nu \gtrsim 1$ GeV) neutrino astronomy, indirect searches for WIMPs and searches for low energy ($E_\nu \gtrsim 7$ MeV) stellar collapse neutrinos. The detector has global dimensions of $12 \times 9.3 \times 76.5$ m$^3$ and provides a total acceptance to an isotropic flux of particles of $\sim 10,000$ m$^2$ sr. The total mass is $\sim 5300$ t. A cross section of the detector is shown in Fig. 1. It has three sub-detectors: liquid scintillation counters, limited streamer tubes and nuclear track detectors. The mean rock depth of the overburden is $\sim 3700$ m.w.e.; the minimum is 3150 m.w.e. This defines the minimum downgoing muon energy at the surface as $\sim 1.3$ TeV in order to reach the underground lab. The average residual energy and the muon flux at the lab depth are $\sim 310$ GeV and $\sim 1$ m$^{-2}$ h$^{-1}$, respectively.

2 Atmospheric $\nu$. Neutrino oscillations.

Neutrino oscillations. For massive neutrinos one has to consider the weak flavour eigenstates ($\nu_e$, $\nu_\mu$, $\nu_\tau$, which are relevant for $\pi \to \mu \nu_\mu$, $K \to \mu \nu_\mu$ and $\mu \to e\nu_\tau\nu_\mu$ decays and for $\nu$ interactions) and mass eigenstates ($\nu_1$, $\nu_2$, $\nu_3$, relevant for propagation). The flavour eigenstates are linear combinations of the mass eigenstates, $\nu_l = \sum_{m=1}^{3} U_{lm} \nu_m$. For two flavours

\[
\begin{cases}
\nu_\mu = \nu_2 \cos \theta + \nu_3 \sin \theta \\
\nu_\tau = -\nu_2 \sin \theta + \nu_3 \cos \theta
\end{cases}
\]

where $\theta$ is the mixing angle. The rate of $\nu_\mu$ disappearance is given by

\[
P(\nu_\mu \to \nu_\mu) \approx 1 - \sin^2 2\theta \sin^2 (1.27 \Delta m^2 L/E_\nu)
\]

$\Delta m^2 = m^2_{\nu_3} - m^2_{\nu_2}$, $L =$ distance (in m) from the decay point to the interaction point.

Only disappearance experiments have been performed until now; the final proof of $\nu$-oscillations will come from appearance experiments, $P(\nu_\mu \to \nu_\tau) = 1 - P(\nu_\mu \to \nu_\mu)$, in which one observes neutrinos which have not been produced in the $\pi, K$ decays.
Figure 1: Event topologies induced by $\nu_\mu$ interactions in and around MACRO. The black boxes are scintillator hits. The track direction and versus are measured by the streamer tubes and time of flight (ToF).

**Atmospheric neutrinos.** Primary cosmic rays produce in the upper atmosphere pions and kaons, which decay, $\pi \rightarrow \mu \nu$, $K \rightarrow \mu \nu$; and $\mu^\pm \rightarrow (\nu_\mu + (\nu_e + e^\pm)$. Neutrinos are produced in a spherical surface, $\sim 10$ km from the Earth, and move towards the Earth.

**Neutrino-induced Upward Going Muons.** They are identified using the streamer tube system (for tracking) and the scintillator system (for time-of-flight (ToF) measurement). A rejection factor of at least $10^5$ is needed in order to separate the up-going muons from the large background coming from down-going muons. Fig. 1 shows three different topologies of neutrino events: up throughgoing muons, semicontained upgoing muons (IU) and up stopping muons+semicontained downgoing muons (UGS+ID). The parent $\nu_\mu$ energy spectra for the three event topologies were computed with Monte Carlo methods. The number of events measured and expected for the three topologies is given in Table 1.

Sources of background and systematic effects were studied in detail in [3] and found to be negligible.

**High energy data.** The up throughgoing muons come from $\nu_\mu$’s interacting in the rock below the detector; the $\nu_\mu$’s have a median energy $E_\nu \sim 50$ GeV. The muons with $E_\mu > 1$ GeV cross the whole detector; the ToF information provided by the scintillation counters allows the determination of their direction (versus).

Fig. 2 shows the zenith angle distribution of the measured flux of up throughgoing muons with energy $> 1$ GeV; the Monte Carlo expectation for no oscillations is shown as a dashed line, and for a $\nu_\mu \rightarrow \nu_\tau$ oscillated flux with $\sin^2 2\theta = 1$ and $\Delta m^2 = 0.0025$ eV$^2$, as a solid line. The data have been compared with Monte Carlo simulations, using the neutrino flux computed by the Bartol group and the cross sections for neutrino interactions calculated using the GRV94 parton distribution; the propagation of muons to the detector was done using the energy loss calculation by Lohmann et al. The total theoretical uncertainty on the expected muon flux is $17\%$; it is mainly a scale error that doesn’t change the shape of the angular distribution. The ratio of the observed number of events to the expectation without oscillations is given in Table 1.

The independent probabilities for obtaining the number of events and the angular distribution observed have been calculated for various parameter values. The value of $\Delta m^2$ obtained from the shape of the angular distribution is equal to the value needed to obtain the observed reduction in the number of events; for $\nu_\mu \rightarrow \nu_\tau$ oscillations the maximum probability is $57\%$, with best parameters $\Delta m^2 = 0.0025$ eV$^2$, $\sin^2 2\theta = 1$. The probability for no-oscillations is $0.4\%$. The probability for $\nu_\mu \rightarrow \nu_{\text{sterile}}$ oscillations is $0.15\%$; combining these probabilities with the measured ratio of horizontal/vertical muons (Fig. 3) we conclude that $\nu_\mu \rightarrow \nu_{\text{sterile}}$ oscillations are disfavoured compared to $\nu_\mu \rightarrow \nu_\tau$. Fig. 4 shows the $90\%$ CL regions for $\nu_\mu \rightarrow \nu_\tau$, computed according to ref. [4].
Figure 2: The black points are the measured fluxes of the up throughgoing muons with $E_\mu > 1$ GeV plotted vs. zenith angle $\theta$. The dashed line is the expectation for no oscillations; it has a 17% scale uncertainty. The solid line is the fit to an oscillated muon flux, obtaining maximum mixing and $\Delta m^2 = 0.0025$ eV$^2$.

Figure 3: The flux ratio vertical/horizontal for upthroughgoing muons. The measured point is plotted at a $\Delta m^2$ around the minimum of $\chi^2$ for $\nu_\mu \rightarrow \nu_\tau$ oscillations.
Figure 4: Confidence regions for $\nu_\mu \rightarrow \nu_\tau$ oscillations at the 90% CL calculated according to [4], obtained from MACRO high energy and low energy data.

| Events     | Predictions (Bartol flux) | R = Data/MC          |
|------------|---------------------------|----------------------|
| Up throughgoing | 768                        | 989                  | $0.731 \pm 0.028_{st} \pm 0.044_{sys} \pm 0.124_{th}$ |
| Internal Up | 135                        | 202                  | $0.55 \pm 0.04_{st} \pm 0.06_{sys} \pm 0.14_{th}$   |
| Up Stop + In Down | 229                        | 273                  | $0.70 \pm 0.04_{st} \pm 0.07_{sys} \pm 0.18_{th}$   |

Table 1: Event summary for the MACRO atmospheric neutrino flux analyses. The ratios R = Data/MC are relative to MC expectations assuming no oscillations (column 3).

**Low energy data.** The *Upgoing semicontained muons* come from $\nu_\mu$ interactions inside the lower apparatus. Since two scintillation counters are intercepted, the ToF is applied to identify the upgoing muons (Fig. 1). The average parent neutrino energy for these events is 4.2 GeV. If the atmospheric neutrino anomalies are the results of $\nu_\mu \rightarrow \nu_\tau$ oscillations with maximum mixing and $\Delta m^2$ between $10^{-3}$ and $10^{-2}$ eV$^2$ one expects a reduction of about a factor of two in the flux of these events, without any distortion in the shape of the angular distribution. This is what is observed in Fig. 5.

The *up stopping muons* are due to external $\nu_\mu$ interactions yielding upgoing muon tracks stopping in the detector; the *semcointained downgoing muons* are due to $\nu_\mu$ induced downgoing tracks with vertices in the lower MACRO (Fig. 1). The events were selected by means of topological criteria; the lack of time information prevents to distinguish the two sub samples, for which an almost equal number of events is expected; the average neutrino energy for these events is $\simeq$ 3.5 GeV. In case of oscillations with the quoted parameters, a reduction in the flux of the up stopping events as the semicontained upgoing muons is expected. No reduction is instead expected for the semicontained downgoing events (coming from neutrinos with path lengths of $\sim 10$ km).

The MC simulation for the low energy data uses the Bartol neutrino flux and the neutrino low energy cross sections of ref. [5]. The number of events and the angular distributions are compared with the predictions in Fig. 1 and Table 1. The measured low energy data show a uniform deficit with respect to the predictions; there is good agreement with the predictions based on neutrino oscillations using the parameters obtained from up throughgoing muons. The allowed region in the $\Delta m^2, \sin^2 2\theta$ plane is shown in Fig. 1.
Using the double ratio $R = \frac{(Data/MC)_{IU}}{(Data/MC)_{ID+UGS}}$ between data and MC of the two low energy data sets, the theoretical uncertainties on neutrino flux and cross sections almost disappear (a residual 5% uncertainty remains due to the small differences between the energy spectra of the two samples). The average value of the double ratio over the measured zenith angle distribution is $R \simeq 0.59 \pm 0.07_{\text{stat}}$. $R = 0.75$ is expected in case of no oscillations, $R = 0.58$ in case of $\nu_\mu \to \nu_\tau$ oscillations.

## 3 High Energy Muon Neutrino Astronomy

The excellent angular resolution of the detector allows a sensitive search for up-going muons produced by neutrinos coming from celestial sources; in this case the atmospheric neutrinos are the main background. The pointing capability of MACRO was demonstrated by the observed "shadows" of the Moon and of the Sun, which produce a "shield" to the cosmic rays. We used a sample of $45 \times 10^6$ downgoing muons, looking at the bidimensional density of the events around the center of the Moon and of the Sun [6]. The density of events shows a depletion with a statistical significance of $5.5 \sigma$ for the Moon and of $4.2 \sigma$ for the Sun. The slight displacements of the maximum deficits are consistent with the deflection of the primary protons due to the geomagnetic field for the Moon and to the combined effect of the magnetic field of the Sun and of the geomagnetic field. The angular resolution, corresponding to a cone angle containing $68\%$ of the events, is $0.9^\circ \pm 0.3^\circ$; it is obtained from double muon events. An excess of events over the atmospheric $\nu$ background was searched for around the positions of known sources in $3^\circ$ (half width) angular bins. This value was chosen so as to take into account the angular smearing produced by the multiple scattering in the rock below the detector and by the energy-integrated angular distribution of the scattered muon, with respect to the neutrino direction. A total of 1197 events was used in this search, see Fig. [6]. No excess was observed; the $90\%$ CL limits on the neutrino fluxes from specific celestial sources are at the level of $\sim 10^{-6} \text{ cm}^{-2} \text{ s}^{-1}$, see Table [6].

We also searched for time coincidences of our upgoing muons with $\gamma$-ray bursts as given in the BATSE 3B and 4B catalogues, for the period April 91 - October 99 [6]. No statistically significant time correlation

Table 2: High energy neutrino astronomy: muon and neutrino flux limits (90 % CL) for selected sources calculated according to the prescription in [4]. Previous best limits (B is for Baksan, I is for IMB) were computed using the classical Poissonian method.

Figure 6: High energy neutrino astronomy. Upgoing muon event distribution in equatorial coordinates (1197 events).
Figure 7: Upward-going muon flux vs neutralino mass \( m_\chi \) for \( E_{\mu}^{th} = 1 \text{ GeV} \) from the Earth. Each dot is obtained varying model parameters. The solid line is the MACRO flux limit (90\% CL); the line for the no-oscillation hypothesis is essentially indistinguishable in the log scale from the one for the \( \nu_\mu \rightarrow \nu_\tau \) oscillation hypothesis (it could be about two times lower). The open circles indicate models excluded by direct measurements (particularly the DAMA/NaI experiment) and assume a local dark matter density of 0.5 GeV cm\(^{-3}\).

was found.

4 Indirect Searches for WIMPs

Weakly Interacting Massive Particles (WIMPs) could be part of the galactic dark matter; they could be intercepted by celestial bodies, slowed down and trapped in their centers. WIMPs and anti-WIMPs could annihilate and yield pions, kaons and then neutrinos of GeV or TeV energy coming from a small angular window from the celestial body centers. The 90\% CL limit for the flux from the Earth center is \( \sim 0.8 \times 10^{-14} \text{ cm}^{-2} \text{ s}^{-1} \) for a \( 10^\circ \) cone around the vertical. The limit from the Sun is \( \sim 1.4 \times 10^{-14} \text{ cm}^{-2} \text{ s}^{-1} \).

If the WIMPs are identified with the lowest mass neutralinos, the MACRO limit constrains the stable neutralino mass, following the models of Bottino et al., see Fig. 7.

5 Neutrinos from Stellar Gravitational Collapses

A stellar gravitational collapse (GC) is expected to produce a large burst of all types of neutrinos and antineutrinos with energies of \( 7 - 30 \text{ MeV} \) for a duration of \( \sim 10 \text{ s} \). The \( \bar{\nu}_e \)'s can be detected via the reaction \( \bar{\nu}_e + p \rightarrow n + e^+ \) in the liquid scintillator. About 100 ÷ 150 \( \bar{\nu}_e \) events would be detected in our 580 t of scintillator for a stellar collapse at the center of our Galaxy. We use two electronic systems for detecting \( \bar{\nu}_e \)'s from stellar gravitational collapses. Both systems have an energy threshold of \( \sim 7 \text{ MeV} \) and record pulse shape, charge and timing informations. Immediately after a trigger, the dedicated system lowers its threshold to about 1 MeV, for a duration of 800 \( \mu \text{s} \), in order to detect (with \( \sim 25\% \) efficiency) the 2.2 MeV \( \gamma \) released in the reaction \( n + p \rightarrow d + \gamma_{2.2 \text{ MeV}} \) induced by the neutron produced in the primary process. A redundant supernova alarm system is in operation: we have defined a general procedure to alert the physics and astrophysics communities in case of an interesting alarm. A procedure to link the various supernovae observatories around the world (MACRO, SuperK, LVD,
SNO, etc.) was set up. Our live-time fraction in the last four years was $\simeq 97.5\%$. No stellar gravitational collapses were observed in our Galaxy since 1989.

6 Conclusions

We presented new MACRO data on upgoing muons of low and high energy. These data are relevant for the study of neutrino oscillations, in particular $\nu_\mu \rightarrow \nu_\tau$.

We discussed the limits obtained from the searches for astrophysical sources of H.E. neutrinos, for WIMPs and for low energy neutrinos from gravitational stellar collapses.
