(Dated: May 23, 2019)

We propose an efficient method for simultaneously learning both the structure and parameter values of quantum circuits with only a small computational overhead. Shallow circuits trained using structure learning perform significantly better than circuits trained using parameter updates alone, making this method particularly suitable for use on noisy intermediate-scale quantum computers. We demonstrate the method for training a variational quantum eigensolver for finding the ground states of Lithium Hydride and the Heisenberg model.

INTRODUCTION

Quantum circuit learning is a method for tuning the parameters of a quantum circuit to perform a specific task. Multiple applications have been demonstrated including in chemical simulation, optimization, generative modeling and classification [1–7].

Typically, circuit learning is performed by selecting a fixed circuit structure, parametrizing it using rotation gates, then iteratively updating the parameters to minimize an objective function estimated from measurements. Circuits of this type are known as parametrized quantum circuits (PQCs). Methods based on quantum circuit learning are particularly promising for use with noisy intermediate-scale quantum (NISQ) computers because of their relative tolerance to noise compared to many other quantum algorithms.

In recent years a lot of progress has been made in improving the performance of PQCs including methods for calculating parameter gradients, hardware efficient ansätze, reducing the number of measurements required, and resolving problems with vanishing gradients [8–12]. Despite progress, many challenges remain. One of the most critical challenges is addressing the effects of noise. Generally, the effects of noise increase with the depth of the quantum circuit. For this reason it is highly desirable for a PQC to be as shallow as possible whilst being expressive enough to perform the task at hand.

Few approaches have been proposed for learning the structure of a quantum circuit. In Ref. [13] the authors propose using a genetic algorithm for learning the circuit structure by selecting candidate gates from a set of allowed gates that are not parametrized. In Ref. [14] the authors propose growing the circuit by iteratively adding parametrized gates and re-training the PQC using gradient descent.

In this work we propose a method for efficiently learning the structure of quantum circuits while variationally optimizing an objective function, for example the energy given by a Hamiltonian operator. Gates are defined so that both the canonical direction and angle of rotation are degrees of freedom. Whilst the angle is parametrized in a continuous manner, the direction is chosen from a set of generators, namely tensor products of Pauli matrices. Training is performed by selecting the first gate and finding the direction and angle of rotation that yield minimum energy. This is performed iteratively for all the parametrized gates in the circuit. Once the last gate has been optimized the cycle is repeated until convergence.

In the Methods section we describe the approach in generality and then provide algorithms for the case of parametrized single-qubit gates and fixed two-qubit gates. This special case is interesting because it can be executed on all existing NISQ hardware and can provide a significant advantage as we show in the Results section. Note that for single-qubit rotations about fixed directions, the optimal angle can be found using 3 energy estimations. Independently from our work this property has been used as part of proposed methods for optimizing angles of rotation in quantum circuits [15, 16]. Our method extends this and finds also the optimal direction within a set of canonical ones. This comes with very little overhead, since only 7 energy estimations are required. We shall stress that although we demonstrate the method on parametrized single-qubit gates and fixed entangling gates, the method is not limited to this case. In the Discussion section we present potential extensions.
METHOD

Let us consider a variational problem where the objective function is encoded in a Hermitian operator $M$ and the candidate solution is encoded in a parametrized quantum circuit $U = U_D \cdots U_1$ acting on an $n$-qubit initial state $\rho$. Each gate is either fixed, e.g., a controlled-Z, or parametrized of the form $U_d = \exp(-\frac{i}{2} \theta_d H_d)$. Here, $\theta_d \in (-\pi, \pi]$ are angles of rotation and $H_d$ are Hermitian and unitary matrices, e.g., tensor products of Pauli matrices. We collect these parameters into a real vector $\theta$ and a vector of matrices $H$, respectively.

Without loss of generality we consider the task of minimizing the objective function which we simply refer to as the energy. Using subscripts to indicate arguments of functions, we can state the variational problem as $(\theta^*, H^*) = \arg\min_{\theta, H} \langle M \rangle_{\theta, H}$, where $\langle M \rangle_{\theta, H} = \text{tr}(MU \rho U^\dagger)$.

To solve the variational problem we present two methods. The first fixes the circuit structure and optimizes only the angles; the second optimizes structure and angles simultaneously. Both methods rely on the fact that the expectation value as a function of an angle of rotation has sinusoidal form. That is, if we fix $H$ as well as all the degrees of freedom in vector $\theta$ except one, say $\theta_d$, we can express the expectation as $\langle M \rangle_{\theta_d} = A \sin(\theta + B) + C$ where $A$, $B$, and $C$ are unknown coefficients. A detailed derivation is provided in the Appendix. Clearly, if we were able to estimate these coefficients, we could also characterize the sinusoidal form. This can be exploited to design circuit learning strategies.

Our first method is a coordinate optimization [17–19] algorithm applied to the angles of rotation. It finds the optimal angle for one gate while fixing all others to their current values, and sequentially cycles through the optimal set of generators, which is clearly a daunting combinatorial problem. The general approach consists of using the expression in Eq. (1) to find minimizers $\theta_d^*(P) = \arg\min_{\theta_d} \langle M \rangle_{\theta_d = \phi, H_d = P}$ for all possible generators $P \in \{I, X, Y, Z\}^\otimes n$. Then, $H_d$ is set to the generator giving lowest energy, and $\theta_d$ is set to the corresponding minimizer. This is repeated for $d = 1, \ldots, D$ to complete a cycle and the algorithm iterates until a stop criterion is triggered.

The above is very general and indeed suffers from combinatorial explosion due to the $4^n$ possible choices for the generator of each gate. However, in practice we shall still comply with the constraints of the underlying NISQ hardware. Since we are not considering compilation of logical gates to physical ones, only a very small subset of generators is available, namely the native gate set of the hardware. For simplicity, we now consider learning the structure of single-qubit gates while employing a fixed layout of two-qubit entangling gates. Figure 1 illustrates the circuit layer and shows an example of how the algorithm updates gate’s generator and angle.

When structure learning is limited to single-qubit gates, the generators can be selected such that $H_d \in \{X, Y, Z\}$. The identity generator is not required because it can be trivially obtained from any other generator by setting the angle to zero. In fact, we can exploit this to reduce the number of circuit evaluations.
per optimization step. According to Eq. (1), each of the three generators requires three circuit evaluations, for a total of 9 evaluations per optimization step. Recalling that \( \phi \) can be chosen at will, we can use \( \phi = 0 \) to obtain the identity gate for all three generators. Since \( \langle M \rangle_{\theta = 0, H = X} = \langle M \rangle_{\theta = 0, H = Y} = \langle M \rangle_{\theta = 0, H = Z} \), we can estimate this quantity only once, effectively reducing the number of evaluations to 7 per optimization step. We call this algorithm \textbf{Rotoselect} and summarize it in Algorithm 2.

![Diagram showing the gradient-free algorithm Rotoselect](image)

**Algorithm 1 Rotosolve**

\begin{algorithm}
\textbf{Input:} Hermitian measurement operator \( M \) encoding the objective function, parametrized quantum circuit \( U \) with fixed structure, stopping criterion
1: Initialize \( \theta_d \in (-\pi, \pi] \) for \( d = 1, \ldots, D \) heuristically or at random
2: repeat
3: \hspace{1em} for \( d = 1, \ldots, D \) do
4: \hspace{2em} Select a value \( \phi \in (-\pi, \pi] \) heuristically or at random
5: \hspace{2em} Estimate \( \langle M \rangle_{\theta = \phi, \psi = \phi + \theta} \) and \( \langle M \rangle_{\theta = \phi - \frac{\pi}{2}} \) from samples
6: \hspace{2em} \( \theta_d \leftarrow -\frac{\pi}{2} - \arctan \left( \frac{2}{\langle M \rangle_{\theta = \phi - \frac{\pi}{2}} - \langle M \rangle_{\theta = \phi + \theta} - \langle M \rangle_{\theta = \phi - \frac{\pi}{2}} + \langle M \rangle_{\theta = \phi - \frac{\pi}{2}} \right) \)
7: until stopping criterion is met
\end{algorithm}

**Algorithm 2 Rotoselect**

\begin{algorithm}
\textbf{Input:} Hermitian measurement operator \( M \) encoding the objective function, parametrized quantum circuit \( U \), stopping criterion
1: Initialize \( \theta_d \in (-\pi, \pi] \) and \( H_d \in \{X, Y, Z\} \) for \( d = 1, \ldots, D \) heuristically or at random
2: repeat
3: \hspace{1em} for \( d = 1, \ldots, D \) do
4: \hspace{2em} Estimate \( \langle M \rangle_{\theta = \psi, H = P} \) for \( \psi \in \{-\frac{\pi}{2}, +\frac{\pi}{2}\} \) and \( P \in \{X, Y, Z\} \), and \( \langle M \rangle_{\theta = 0} \)
5: \hspace{2em} Compute minimizers \( \theta_d(P) \) for \( P \in \{X, Y, Z\} \) using Eq. (1)
6: \hspace{2em} \( H_d \leftarrow \arg \min_P \langle M \rangle_{\theta = \theta_d(P)} \)
7: \hspace{2em} \( \theta_d \leftarrow \theta_d(H_d) \)
8: until stopping criterion is met
\end{algorithm}

Note that on a quantum computer the objective function is stochastic since \( \langle M \rangle_{\theta, H} \) is estimated from samples. For implementation in NISQ computers the operator is typically described as the weighted sum of polynomial terms \( M = \sum_i w_i M_i \). In this case the expectation is given by \( \langle M \rangle_{\theta, H} = \sum_i w_i \langle M_i \rangle_{\theta, H} \).

We conclude this Section with a note about convergence. Assuming an infinite number of measurements, the objective \( \langle M \rangle_{\theta_d} \) is a deterministic function of \( \theta_d \). Bertsekas [17] provides convergence results for coordinate minimization algorithms under rather general conditions and including non-convex objective functions.
An analysis along these lines could be attempted for Rotosolve. In Rotoselect the analysis is complicated by the fact that multiple generators could lead to equally good minima. That is, at each given optimization step the solution may not be unique. Finally, in practice the objective function is stochastic and this further complicates the analysis.

RESULTS

The impact of structure learning on circuit performance is studied by comparing Rotoselect and Rotosolve, which are identical except that Rotoselect employs structure learning. For this reason any difference in performance can be attributed to structure learning. Note that in the Appendix we compare Rotosolve against other state-of-the-art optimizers and find it to be significantly better in terms of performance and scaling behavior.

First we compare the two algorithms for training a circuit ansatz to find the ground state energy of the 5-qubit Heisenberg model on a 1D lattice with periodic boundary conditions and in the presence of an external magnetic field. The corresponding Hamiltonian reads

\[ M = J \sum_{(i,j) \in E} (X_i X_j + Y_i Y_j + Z_i Z_j) + h \sum_{i \in V} Z_i, \]  

where \( G = (V, E) \) is the undirected graph of the lattice with 5 nodes, \( J \) is the strength of the spin-spin interactions, and \( h \) is to the strength of the magnetic field in the \( Z \)-direction. For \( J/h = 1 \) the ground state is known to be highly entangled (see Ref. [9] for VQE simulations on the Heisenberg model). We chose \( J = h = 1 \).

Circuits were initialized using the strategy described in Ref. [12]. The circuit form consisted of layers of parametrized single-qubit rotations followed by a ladder of controlled-Z gates. The form of the layer is shown in Fig. 1. Training was performed for 1000 iterations.

Figure 2 reports mean and variance of the lowest energy encountered during training across 10 trials for circuits with 6, 9, 12 and 15 layers. Panel (a) shows results when 1000 measurements were used to estimate the expectation of each term in the sum in Eq. (2), while panel (b) shows oracular results in the limit of infinite measurements. For all number of layers, circuits trained using Rotoselect achieved better mean, variance, and absolute lowest energy than circuits trained using Rotosolve. In particular for the lower depth circuits Rotoselect achieves a much smaller variance than Rotosolve. This is likely due to the fact that the generators are initialized at random and Rotosolve is unable to change an initial bad condition. Given the limited capacity of low-depth circuits, a good choice for the generators appears to be particularly important. As the number of layers increases, both algorithms find better approximations to the ground state. Both algorithms exhibit robustness to the finite number of measurement employed here.

The experiment was repeated using the chemical Hamiltonian for Lithium Hydride (LiH) at bond distance. For this Hamiltonian we used the coefficients and Pauli terms given in the Appendix of Ref. [9]. Figure 3 shows results that are consistent with the previous experiment.

DISCUSSION

The proposed algorithms can be extended in a number of ways. In the context of circuit learning, Rotosolve can be generalized to find minimizers of \( K \) angles of rotation at the same time and at the cost of evaluating \( 3^K \) circuits. While this is an exponential cost, for small \( K \) this approach is computationally feasible and may provides an advantage. In Ref. [16] the authors explore this idea for \( K \in \{1, 2, 3\} \) where subsets of angles are chosen at random. This approach belongs to the class of algorithms called coordinate block minimization [19].

In the context of circuit structure learning, Rotoselect can be generalized to incrementally grow circuits from scratch rather than starting from random initial structures. This is similar in spirit to Adapt-VQE [14], but with the advantage that each new gate is optimized efficiently in closed form rather than using gradient-based optimization. Furthermore, we could efficiently remove gates by assessing whether they are contributing to the solution (e.g., a redundant gate would generate sinusoidal forms that appear to be flat).
Another interesting extension is to use Rotoselect to learn the optimal connectivity layout for the entangling gates. As an example consider trapped ion computers that can implement fully connected layers of Mølmer-Sørensen gates [20]. This choice provides high expressive power in low-depth circuits [4], but must be balanced against the slow clock speed of these entangling gates [21] and potential gate errors. Our algorithm could find this sweet spot. Since with \( n \) qubits we must evaluate \( n(n-1)/2 \) choices for non-directional two-qubit gates in a layer, this approach is also efficient.

Beyond quantum circuits, Rotoselect can be used to learn the structure of parametrized tensor networks in both classical and quantum models.

Finally, heuristics can be used to speedup our methods. In our simulations we found that Rotoselect tends to change the structure only in the early stage of training. We could detect this and switch from Rotoselect to Rotosolve hence reducing the number of circuit evaluations.

Quantum circuit structure learning coupled with coordinate minimization algorithms provides an efficient means for improving the expressivity of low-depth quantum circuits with only a small computational overhead. This characteristic makes the described methods particularly suitable for deployment on near-term quantum computers where circuit depth and training time are significant bottlenecks.

Sinusoidal form of expectation values

Recall that we consider circuits $U = U_D \cdots U_1$ where each gate is either fixed, e.g., the controlled-Z, or parametrized as

$$U_d = \exp \left( -\frac{i}{2} \theta_d H_d \right) = \cos \left( \frac{\theta_d}{2} \right) I - i \sin \left( \frac{\theta_d}{2} \right) H_d,$$

where $\theta_d \in (-\pi, \pi]$ and $H_d$ is a Hermitian and unitary matrix such that $H_d^2 = I$. For the latter, we could use tensor products of Pauli matrices $H_d \in \{I, X, Y, Z\}^n$ as generators where $n$ is the number of qubits. We apply the circuit to a fiducial state $\bar{\rho}$ and then measure a Hermitian operator $\bar{M}$ encoding the objective function of the variational problem. From measurement outputs we can estimate the expectation with the donation of the Titan Xp GPU used for this research.

$$\langle \bar{M} \rangle = \text{tr} \left( \bar{M} U_D \cdots U_d \cdots U_1 \bar{\rho} U_1^\dagger \cdots U_d^\dagger U_D^\dagger \right).$$

We want to analyse this expectation as a function of a single parameter $\theta_d$. To simplify the notation we absorb all gates before $U_d$ in the density operator, that is $\rho = U_{d-1} \cdots U_1 \bar{\rho} U_1^\dagger \cdots U_{d-1}^\dagger$. Similarly, we absorb all gates after $U_d$ in the measurement operator $M = U_{d+1}^\dagger \cdots U_D^\dagger MU_D \cdots U_{d+1}$. This can be done because unitary transformations preserve the Hermiticity of both density and measurement operators. Using this notation Eq. (4) can be written as $\langle M \rangle = \text{tr} \left( MU_d \bar{\rho} U_d^\dagger \right)$.

In the following discussion we will need to evaluate the expectation at different parameter values for gate $U_d$. A further change in notation helps. From now on, we drop index $d$ and use subscripts to indicate parameter value. Using the new notation we write

$$\langle M \rangle_\theta = \text{tr} \left( MU_\theta \bar{\rho} U_\theta^\dagger \right) = \text{tr} \left( M \left( \cos \left( \frac{\theta}{2} \right) I - i \sin \left( \frac{\theta}{2} \right) H \right) \bar{\rho} \left( \cos \left( \frac{\theta}{2} \right) I + i \sin \left( \frac{\theta}{2} \right) H \right) \right)$$

$$= \cos^2 \left( \frac{\theta}{2} \right) \text{tr} \left( M \rho \right) + i \sin \left( \frac{\theta}{2} \right) \cos \left( \frac{\theta}{2} \right) \text{tr} \left( M \rho H \right) + \sin^2 \left( \frac{\theta}{2} \right) \text{tr} \left( MH \rho H \right).$$

Let us inspect the third line of this equation. First, we note that $\text{tr}(M \rho)$ is simply the expectation when the circuit is evaluated at $\theta = 0$. That is, $\langle M \rangle_0 = \text{tr}(M \rho)$. Second, the term $i \text{tr}(M \rho H)$ can be written as the difference of two expectations. Indeed, using two independent circuits $U_\pm = \exp \left( \mp \frac{\theta}{2} H \right) = \frac{1}{\sqrt{2}} (I \mp i H)$ we have

$$\langle M \rangle_+ - \langle M \rangle_- = \text{tr} \left( MU_+ \bar{\rho} U_+^\dagger \right) - \text{tr} \left( MU_- \bar{\rho} U_-^\dagger \right)$$

$$= \frac{1}{2} \left( \text{tr} \left( M (I - i H) \rho (I + i H) \right) - \text{tr} \left( M (I + i H) \rho (I - i H) \right) \right)$$

$$= -i \text{tr} \left( MH \rho \right) + i \text{tr} \left( M \rho H \right)$$

$$= i \text{tr} \left( M \rho, H \right).$$

Third, the last term $\text{tr}(MH \rho H)$ is the expectation obtained evaluating the circuit at $\theta = \pi$. That is, using circuit $U_\pi = \exp \left( -\frac{\pi}{2} H \right) = -i H$ we have $\langle M \rangle_\pi = \text{tr}(M \rho H)$.
Putting these three pieces back in Eq. (4) and using well known trigonometric identities, we obtain

\[
\langle M \rangle_\theta = \cos^2 \left( \frac{\theta}{2} \right) \langle M \rangle_0 + \sin \left( \frac{\theta}{2} \right) \cos \left( \frac{\theta}{2} \right) \left( \langle M \rangle_\frac{\pi}{2} - \langle M \rangle_{-\frac{\pi}{2}} \right) + \sin^2 \left( \frac{\theta}{2} \right) \langle M \rangle_\pi
\]

\[
= \frac{1+\cos(\theta)}{2} \langle M \rangle_0 + \frac{\sin(\theta)}{2} \left( \langle M \rangle_\frac{\pi}{2} - \langle M \rangle_{-\frac{\pi}{2}} \right) + \frac{1-\cos(\theta)}{2} \langle M \rangle_\pi
\]

\[
= \frac{\cos(\theta)}{2} \left( \langle M \rangle_0 - \langle M \rangle_\pi \right) + \frac{\sin(\theta)}{2} \left( \langle M \rangle_\frac{\pi}{2} - \langle M \rangle_{-\frac{\pi}{2}} \right) + \frac{1}{2} \left( \langle M \rangle_0 + \langle M \rangle_\pi \right).
\]

(7)

We now use the identity \( a \cos(x) + b \sin(x) = \sqrt{a^2 + b^2} \sin(x + \arctan \left( \frac{a}{b} \right)) \) to obtain a compact expression. The expectation value then reads

\[
\langle M \rangle_\theta = A \sin(\theta + B) + C,
\]

\[
A = \frac{1}{2} \sqrt{\left( \langle M \rangle_0 - \langle M \rangle_\pi \right)^2 + \left( \langle M \rangle_\frac{\pi}{2} - \langle M \rangle_{-\frac{\pi}{2}} \right)^2},
\]

\[
B = \arctan 2 \left( \langle M \rangle_0 - \langle M \rangle_\pi, \langle M \rangle_\frac{\pi}{2} - \langle M \rangle_{-\frac{\pi}{2}} \right),
\]

\[
C = \frac{1}{2} \left( \langle M \rangle_0 + \langle M \rangle_\pi \right).
\]

(8)

That is, the expectation of \( M \) as a function of a single parameter has sinusoidal form with amplitude \( A \), phase \( B \), intercept \( C \), and period \( 2\pi \). An example is shown in Figure 4.

Note that we must use the arctan2 function in order to correctly handle the sign of numerator and denominator, as well as the case where the denominator is zero. To see why, assume \( H \) commutes either with \( M \) or \( \rho \). Then, Eq. (6) evaluates to zero which in turn triggers a division by zero inside the standard arctan.

Now, from the graph of the sine function, it is easy to locate the minima at \( \theta^\ast = -\frac{\pi}{2} - B + 2\pi k \) for all \( k \in \mathbb{Z} \). In Eq. (8), it appears as if we had to evaluate four distinct circuits in order to estimate \( B \). Using simple trigonometry we generalize the estimator for \( B \) and show that only three evaluations are required. Let us write

\[
\langle M \rangle_{\theta+\pi} = A \sin(\theta + \pi + B) + C = -A \sin(\theta + B) + C = -\langle M \rangle_\theta + 2C.
\]

(9)

Solving for \( C \) we have

\[
C = \frac{1}{2} \left( \langle M \rangle_{\theta+\pi} + \langle M \rangle_\theta \right).
\]

(10)

FIG. 4. Expectation and variance of Hermitian observable \( ZXZX \) as a function of two different angles of rotation in a random circuit. The expectation value is always of sinusoidal form with period \( 2\pi \). (a) The variance is large because this angle cannot yield an eigenstate of \( ZXZX \). (b) Both expectation and variance are minimized by setting this second angle to \( \theta^\ast \approx -0.5 \).
Then, we can write
\[
\tan (\phi + B) = \frac{\sin (\phi + B)}{\sin (\phi + B - \frac{\pi}{2})} = \frac{\langle M \rangle_\phi - C}{\langle M \rangle_\phi - \frac{\pi}{2} - C} = \frac{2 \langle M \rangle_\phi - \langle M \rangle_\phi + \frac{\pi}{2} - \langle M \rangle_\phi - \frac{\pi}{2}}{\langle M \rangle_\pi + \frac{\pi}{2} - \langle M \rangle_\pi - \frac{\pi}{2}},
\]
where we substituted Eq. (10) evaluated at \( \theta = \phi - \frac{\pi}{2} \) for \( C \). Taking the inverse tangent we obtain the general estimator for \( B \) requiring only three circuit evaluations. The minimizer can then be found using the closed form expression
\[
\theta^* = \arg \min_{\theta} \langle M \rangle_{\theta} = -\frac{\pi}{2} - \arctan2 \left( 2 \langle M \rangle_{\theta=\phi} - \langle M \rangle_{\theta=\phi + \frac{\pi}{2}} - \langle M \rangle_{\theta=\phi - \frac{\pi}{2}} \right) + 2\pi k,
\]
where \( \phi \in \mathbb{R} \) and \( k \in \mathbb{Z} \). Note that in practice we chose \( k \) such that \( \theta^* \in (-\pi, \pi] \).

**Comparison of optimization algorithms and scaling**

In this experiment we compare the training time and training time scaling in the system size for Rotosolve compared to SPSA and Adam for training quantum circuits [22, 23].

Fig. 5 (a) shows the energy and standard deviation as a function of the number of energy evaluations across 5 trials for the 5-qubit Heisenberg cyclic spin chain described in the Results section. The circuit ansatz used had a fixed structure and is described in Ref. [10]. The depth of the circuit was 30 layers. The exact energy was used to perform updates. The learning rate for Adam was set to 0.05. The hyperparameter for SPSA were the same as in Ref. [9]. Rotosolve converged with significantly fewer energy evaluations than Adam or SPSA.

Fig. 5 (b) shows the mean and standard deviation for the number of evaluations taken to find the ground state of the Heisenberg cyclic spin chain Hamiltonian described in Eq. (2) as a function of the size of the system. 5 trials were performed to estimate the mean and standard deviation. The circuit ansatz was the same as for (a). 1000 measurements were performed on each Hamiltonian term to approximate the energy for each evaluation. Circuit depth was \( n^2 \) for an even number of qubits and \( \frac{n^2-1}{2} \) for odd where \( n \) was the number of qubits. Convergence to solution was set to be an energy less than 0.02 where the range of the spectrum was normalized to be between 0 and 1. Rotosolve was faster to converge than Adam or SPSA for the number of qubits tested.

Rotoselect was not tested in this experiment as a fixed ansatz was used. However, Rotoselect and Rotosolve were found to have similar time to convergence for the experiments described in Fig. 2 and Fig. 3.
