The concept of Floquet engineering is to subject a quantum system to time-periodic driving in such a way that it acquires interesting novel properties. It has been employed, for instance, for the realization of artificial magnetic fluxes in optical lattices and, typically, it is based on two approximations. First, the driving frequency is assumed to be low enough to suppress resonant excitations to high-lying states above some energy gap separating a low energy subspace from excited states. Second, the driving frequency is still assumed to be large compared to the energy scales of the low-energy subspace, so that also resonant excitations within this space are negligible. Eventually, however, deviations from both approximations will lead to unwanted heating on a time scale \( \tau \). Using the example of a one-dimensional system of repulsively interacting bosons in a shaken optical lattice, we investigate the optimal frequency (window) that maximizes \( \tau \). As a main result, we find that, when increasing the lattice depth, \( \tau \) increases faster than the experimentally relevant time scale given by the tunneling time \( \hbar/J \), so that Floquet heating becomes suppressed.

I. INTRODUCTION

The idea of Floquet engineering is to subject a quantum system to time-periodic driving in such a way that it acquires interesting novel properties that are difficult to achieve by other means. This concept has been applied very successfully to systems of atomic quantum gases in optical lattices [1]. The fact that these systems are extremely clean, well isolated from their environment, and highly tunable also in a time-dependent fashion makes them an ideal platform for studying coherent many-body dynamics. Examples for Floquet engineering in optical lattices include, among others, dynamic localization [2,3], photon-assisted tunneling [4,8], the control of an interaction-induced quantum phase transition [9,10], the creation of kinetic frustration [11,12], artificial magnetic fields [13,22], topological band structures [23,25], and number dependent gauge potentials [26].

A simple explanation of the basic concept underlying Floquet engineering is often given by considering the one-cycle time-evolution operator

\[
\hat{U}(T,0) = \mathcal{T} \exp \left( \frac{i}{\hbar} \int_0^T dt \hat{H}(t) \right) \tag{1}
\]

for a quantum system described by a time-periodic Hamiltonian with angular driving frequency \( \omega = 2\pi/T \),

\[
\hat{H}(t) = \hat{H}(t+T), \tag{2}
\]

where \( \mathcal{T} \) denotes time ordering. The fact that this operator is unitary allows one, at least formally, to express it in terms of an hermitian operator \( \hat{H}_F \) that is called Floquet Hamiltonian,

\[
\hat{U}(T,0) = \exp \left( \frac{i}{\hbar} T \hat{H}_F \right). \tag{3}
\]

This effective time-independent Hamiltonian \( \hat{H}_F \) governs the time evolution of the system, when it is monitored stroboscopically in integer steps of the driving period \( T \). Thus, at a first glance, one might expect that the driven system behaves as some effective non-driven system described by the Hamiltonian \( \hat{H}_F \). However, while the above reasoning applies to small quantum systems, the situation in many-body systems is more complex. Here the eigenstates of \( \hat{H}_F \) will typically be superpositions of states having very different energies. This is a consequence of the lack of energy conservation in driven systems, which is reflected in the possibility of resonant coupling, and the fact that in a large system resonances will be ubiquitous. The lack of energy conservation suggests that in the thermodynamic limit the system approaches an infinite-temperature-like state, so that in the sense of eigenstate thermalization the eigenstates of \( \hat{H}_F \) represent an infinite-temperature ensemble [27,28]. From this point of view, the Floquet Hamiltonian \( \hat{H}_F \) does not seem to be a suitable object for engineering interesting system properties.

The fact that Floquet engineering can, nevertheless, be a useful concept also in many-body quantum systems, is related to the observation that in some parameter regimes the time scale \( \tau \) associated with unwanted resonant processes, where the system absorbs (or emits) energy quanta \( \hbar \omega \), can become rather long. Since typically energy absorption dominates, in the following, we will denote such detrimental energy-non-conserving processes as “heating” and \( \tau \) as the corresponding “heating” time [29]. On times shorter than \( \tau \), we might be able to engineer and study interesting driving-induced physics described by an approximate time-independent effective Hamiltonian \( \hat{H}_{eff} \), corresponding to a non-driven system with modified properties. The standard strategy employed for deriving such an effective Hamiltonian involves two steps [3]:

The first step is given by a low-frequency approximation, where the assumption is made that the system remains in a low-energy subspace, which is separated by

Hamiltonian $\hat{H}_{\text{eff}}$ acting in the lowest Bloch band to the evolution obtained from integrating the dynamics of the fully time-dependent model that, apart from the lowest band, contains also first excited band.

The remaining part of this paper is organized as follows: After introducing the system and the model in Sec. II in Sec. III we recapitulate the derivation of the approximate effective Hamiltonian $\hat{H}_{\text{eff}}$ from the low and the high-frequency approximation. In the following two sections, we then compare the evolution generated by $\hat{H}_{\text{eff}}$ to numerical simulations: in Sec. IV we investigate the breakdown of the high-frequency approximation due to intraband heating and in Sec. V we study the combined effect of intraband and interband heating beyond the high and low frequency approximation. Finally, we close with Sec. VI.

II. SYSTEM AND MODEL

We consider a system of ultracold bosonic atoms in a one-dimensional optical lattice potential

$$V(r) = V_0 \sin^2(k_L x) + V_\perp(y, z).$$

(4)

Here the laser wave number $k_L$ defines the recoil energy $E_R = \hbar^2 k_L^2 / (2m)$ with atom mass $m$, corresponding to the kinetic energy required to localize a particle on the length of a lattice constant $a = \pi/k_L$. Typical recoil energies take values of a few kHz. The deep confining potential $V_\perp(y, z) \sim \frac{\hbar^2}{2} \omega_\perp^2 (y^2 + z^2)$ shall reduce the dynamics to one spatial dimension via a large transverse excitation gap $\hbar \omega_\perp$ that freezes the particles in the lowest transverse single-particle state. More precisely, $\omega_\perp$ will be chosen large enough, so that the time scale for driving induced transverse heating can be expected to be much longer than the one for resonant excitations of longitudinal degrees of freedom in lattice direction, which we are going to investigate here.

The system shall be driven periodically in time by the homogenous sinusoidal force pointing in the lattice direction $e_x$,

$$F(t) = -K a \cos(\omega t) e_x.$$  

(5)

It is characterized by the driving strength $K$, corresponding to the amplitude of the potential offset between neighboring lattice sites, and the angular driving frequency $\omega$, which defines also the driving period $T = 2\pi / \omega$. Such a force can be realized as an inertial force by shaking the lattice back and forth in $x$ direction.

In the absence of periodic forcing, experiments performed in the regime of deep lattices, $V_0/E_R \gtrsim 5$, at the typical ultracold quantum gas temperatures are described accurately by the single-band Bose Hubbard model [40]

$$\hat{H}_s = -J_s \sum_{\ell=1}^{M-1} \left( \hat{b}^\dagger_{s,\ell+1} \hat{b}_{s,\ell} + \text{H.c.} \right) + \frac{U_s}{2} \sum_{\ell=1}^{M} \hat{n}_{s,\ell} (\hat{n}_{s,\ell} - 1).$$

(6)
Here the index $\ell$ denotes the lattice sites in ascending order from 1 to $M$ and the label $s$ indicates the lowest Bloch band to be distinguished from the first excited band, labeled by $p$, which is considered below. Moreover, $\hat{b}_{s\ell}^\dagger$, $\hat{b}_{s\ell}$, and $\hat{n}_{s\ell} = \hat{b}_{s\ell}^\dagger \hat{b}_{s\ell}$ denote the creation, annihilation and number operator for a boson in a Wannier state of band $s$ on site $\ell$. Nearest-neighbor tunneling is described by the parameter $J_s$ and on-site interactions by the Hubbard parameter $U_s$.

While in a non-driven system, a description in the low-energy subspace of the $s$ band is well justified, this assumption is not as clear in a system that is driven periodically. Even if the driving frequency is small compared to the band gap separating the $s$ band from the first excited $p$ band, states of excited bands might still be populated via multiphoton excitations corresponding to either single-particle processes \cite{21,36} or two-particle scattering \cite{27}. If periodic driving is used to control the physics of the lowest band, such excitation processes must be viewed as unwanted heating. In order to estimate this effect, we will also take into account the first excited band, which for the undriven lattice is captured by the Hamiltonian

$$
\hat{H}_p = \Delta \sum_{\ell=1}^M \hat{n}_{p\ell} + J_p \sum_{\ell=1}^{M-1} \left( \hat{b}_{p\ell}^\dagger \hat{b}_{p\ell+1} + H.c. \right) + \frac{U_p}{2} \sum_{\ell=1}^M \hat{n}_{p\ell}(\hat{n}_{p\ell} - 1),
$$

and coupled to the $s$ band via the interband interaction term

$$
\hat{H}_{sp} = U_{sp} \sum_{\ell=1}^M \left[ 2\hat{n}_{s\ell}\hat{n}_{p\ell} + \frac{1}{2} \left( \hat{b}_{p\ell}^\dagger \hat{b}_{p\ell} \hat{b}_{s\ell}^\dagger \hat{b}_{s\ell} + H.c. \right) \right].
$$

Here $\Delta$ denotes the orbital energy required to excite a particle to a Wannier state of the $p$ band and $J_p$ and $U_p$ describe nearest-neighbor tunneling and on-site interactions in this $p$ band, respectively. The on-site scattering and repulsion between $s$ and $p$ states is quantified by $U_{sp}$.

If the energy scales of the periodic force, $\hbar\omega$ and $K$, remain below the band gap $\Delta$, the bands of the undriven problem, $s$ and $p$, provide a useful basis also for the description of the driven system (see supplemental material of Ref. \cite{27}). Assuming this regime, we project the potential $-\mathbf{r} \cdot \mathbf{F}(t)$ induced by the force to the lowest two bands and obtain the driving term of the Hamiltonian:

$$
\hat{H}_{dr}(t) = K \cos(\omega t) \sum_{\ell=1}^M \left[ \ell \left( \hat{n}_{s\ell} + \hat{n}_{p\ell} \right) + \eta \left( \hat{b}_{p\ell}^\dagger \hat{b}_{s\ell} + H.c. \right) \right]
$$

where $\eta$ is the dipole matrix element between two Wannier states of the $s$ and the $p$ band on the same lattice site in units of the lattice constant.

The total Hamiltonian to be used for our analysis is now given by

$$
\hat{H}(t) = \hat{H}_s + \hat{H}_p + \hat{H}_{sp} + \hat{H}_{dr}(t).
$$

The number of independent parameters that describe this model is reduced considerably by noticing that $J_s/E_R$, $J_p/E_R$, $\Delta/E_R$, and $\eta$ are determined completely by the dimensionless lattice depth $V_0/E_R$. Moreover, the interaction parameters $U_s$, $U_p$, and $U_{sp}$ share the very same (linear) dependence on both the $s$-wave scattering length $a_s$ (which can be tuned using Feshbach resonances) and the transverse confinement $\omega_\perp$, so that their ratios $U_p/U_s$ and $U_{sp}/U_s$ equally depend on $V_0/E_R$ only. Thus, taking $J_s$ and $\hbar\omega/J_s$ as the units for energy and time, respectively, the undriven model is characterized by $V_0/E_R$ and $U_s/J_s$ as well as by the average number of particles per site $N/M$. The periodic driving is furthermore characterized by the dimensionless driving strength $K/J_s$ and angular frequency $\omega_\perp$. The dependence of the model parameters on the lattice depth $V_0/E_R$, obtained from band-structure calculations, is shown in Fig. 1.

III. THE LOW AND THE HIGH-FREQUENCY APPROXIMATION

Most schemes of Floquet engineering in optical lattices (such as for example the control of the bosonic Mott transition \cite{9,10}, the implementation of kinetic frustration \cite{11,12}, the creation of artificial gauge fields \cite{13,15-19,22}, and the realization of Floquet topological insulators \cite{23,24}) are based on two approximations: a low-frequency approximation with respect to orbital degrees of freedom and a high-frequency approximation with respect to processes occurring in the lowest band described by $H_s$.

The low-frequency single-band approximation is based on the assumption that the driving frequency and amplitude remain low enough to ensure that the system remains in the subspace spanned by the lowest (s-type) Wannier-like orbital at each lattice site. It roughly re-
quires driving frequencies
\[ \hbar \omega \ll \Delta \] (11)
and driving amplitudes \( K \) smaller than a threshold value \( K_{th} \) below which multiphoton transitions are expected to be suppressed exponentially with the photon number \( \Delta/\hbar \omega \) [30]. It leads to a description of the system in terms of a tight-binding model with a single orbital state per lattice site, which in our case is given by the single-band model
\[ \hat{H}_{ab}(t) = \hat{H}_s + K \cos(\omega t) \sum_{\ell=1}^{M} \ell \hat{n}_{s\ell}. \] (12)

The high-frequency approximation is based on the assumption that the driving frequency is still large compared to the energy scales \( J_s \) and \( U_s \) governing the low-energy model [12],
\[ \hbar \omega \gg J_s, U_s. \] (13)
Under these conditions the resonant creation of collective excitations of energy \( \hbar \omega \) becomes a slow high-order process that can be neglected on sufficiently short time scales. This allows us to describe the system using an approximate effective time-independent Hamiltonian obtained from a high-frequency expansion [9, 41, 44, 45]. For that purpose, we first perform a gauge transformation with the time-periodic unitary operator
\[ \hat{U}(t) = \exp \left( -i \sum_{\ell=1}^{M} \theta(t) \ell \hat{n}_{s\ell} \right) \] (14)
with \( \theta(t) = K/(\hbar \omega) \sin(\omega t) \ell \), which integrates out the driving term. The transformed Hamiltonian \( \hat{H}' = \hat{U}^{\dagger} \hat{H}_{ab} \hat{U} - i \hat{U}^{\dagger} \dot{\hat{U}} \) reads
\[ \hat{H}'(t) = -J_s \sum_{\ell=1}^{M-1} \left( e^{i \theta(t)} \hat{b}_{s\ell+1}^{\dagger} \hat{b}_{s\ell} + \text{H.c.} \right) \]
\[ + U_s \sum_{\ell=1}^{M} \hat{n}_{s\ell}(\hat{n}_{s\ell} - 1). \] (15)
The fact that it possesses typical matrix elements that are are small compared to \( \hbar \omega \) even for large \( K \sim \hbar \omega \) justifies the high-frequency approximation also for strong driving. Its leading order is given by the rotating-wave approximation, where the system is described by the time-averaged Hamiltonian
\[ \hat{H}_{\text{eff}} = \frac{1}{T} \int_{0}^{T} dt \hat{H}'(t) dt \] (16)
\[ = -J_s \sum_{\ell=1}^{M-1} \left( \hat{b}_{s\ell+1}^{\dagger} \hat{b}_{s\ell} + \text{H.c.} \right) + \frac{U_s}{2} \sum_{\ell=1}^{M} \hat{n}_{s\ell}(\hat{n}_{s\ell} - 1). \]
Here the effective tunneling matrix element
\[ J_s^{\text{eff}} = J_s J_0(K/\hbar \omega) \] (17)
aquired a dependence on the scaled driving amplitude \( K/(\hbar \omega) \) described by a Bessel function \( J_n \). In this way the time evolution of the system’s state \( |\psi(t)\rangle \) is approximately described by
\[ |\psi(t)\rangle \approx \hat{U}(t) e^{-\frac{i}{\hbar}(t-t_0)\hat{H}_{\text{eff}}} \hat{U}^{\dagger}(t_0) |\psi(t_0)\rangle. \] (18)
In particular, we expect
\[ |\psi(nT)\rangle \approx e^{-\frac{i}{\hbar}nT \hat{H}_{\text{eff}}} |\psi(0)\rangle \equiv |\psi^{\text{eff}}_n\rangle \] (19)
for integers \( n \), when monitoring the dynamics stroboscopically in steps of the driving period at those times \( t = nT \), for which \( \hat{U}(nT) = 1 \). Higher orders of the high-frequency expansion will provide relative corrections of the order of \( J_s/\hbar \omega \) to the evolution governed by \( \hat{H}_{\text{eff}} \) [11, 44].

The single-band high-frequency approximation, leading to a description of the system’s dynamics in terms of the approximate effective Hamiltonian (16), requires that there is a window of driving frequencies for which both conditions (11) and (13) are fulfilled. Since with increasing lattice depth \( V_0/E_R \) both \( J_s \) decreases rapidly and \( \Delta \) increases moderately (see Fig. 1), while the interaction parameter \( U_s \) can be made small by tuning the \( s \)-wave scattering length using a Feshbach resonance, such a window will open for sufficiently large \( V_0/E_R \). However, even within such a frequency window heating will not be suppressed completely and eventually make itself felt on some time scale \( \tau \). This heating time \( \tau \) has to be compared to the typical duration of an experiment, which will be given by some fixed multiple of the tunneling time \( h/J_s \), which in turn increases exponentially with the lattice depth [asymptotically for deep lattices \( \ln(J_s/E_R) \approx -2\sqrt{V_0/E_R} \) [47], see also Fig. 1]. Thus, in order to take into account also this latter effect, in the following we will investigate the behavior of the dimensionless heating time \( \tau_{\text{seven}}/h \). In doing so, we have to keep in mind that there will also be background heating (resulting from noise, three-body collisions, or scattering with background particles), which is independent of the periodic driving and happens on some time scale \( \tau_0 \). Assuming \( \tau_0 \sim 1\text{s} \) (\( \sim 10\text{s} \)), requiring \( \tau_0 \gg h/J_s \), and noting that \( E_R \sim 2\pi \cdot h \) kHz for typical experiments, we can see from Fig. 1 that the lattice depth is limited to values \( V_0/E_R \lesssim 15 \) (20).

**IV. INTRABAND HEATING**

Let us first investigate the validity of the high-frequency approximation, before considering also heating due to the coupling to the first excited band. For this purpose we consider the following quench scenario. We assume that the system is prepared in the ground state of the undriven Hamiltonian (6), when at time \( t = 0 \) the driving amplitude is switched on abruptly to a finite value \( K \). We integrate the time evolution of the system described by the time-dependent single-band Hamiltonian
\[ \Delta n(t) = n_0(t) - n_0^{\text{eff}}(t) \]
FIG. 3. Heating time $\tau$ (dots) versus driving frequency $\hbar\omega/J_s$ for two different values of the interaction strength $U_s/J_s$. The other parameters are chosen as in Fig. 2: $N = 6$, $M = 10$, $K/\hbar\omega = 4$, and $V_R/E_R = 14$. The solid lines are exponential fits.

V. INTRABAND AND INTERBAND HEATING

The exponential increase of the heating time with respect to the driving frequency visible in Fig. 3 is an artifact of the single-band description of the driven lattice system. Namely, for sufficiently large driving frequencies unwanted excitations to higher-lying orbital states (spanning excited Bloch bands) will become the dominant heating effect. In order to take into account this effect, we will include also the coupling to the $p$-band. For this purpose we consider the two-band Hamiltonian (10) and monitor the heating time $\tau$ defined in the same way as in the previous section. In an experiment, of course, also further (higher-lying) bands will play a role. However, the coupling to the first excited band is most dominant, because with respect to the lowest band it both is energetically closest and possesses the largest coupling matrix elements. Therefore, the characteristic time scale for interband heating processes is determined by transitions to the $p$ band. Higher-lying bands can still make themselves felt, e.g. in the precise shape of resonance lines (as discussed in Ref. [31]). However, such details are not crucial for the present analysis, which is interested in the time scales only.

In Fig. 4 we plot the heating time $\tau$ versus the driving frequency for a system of $N = 4$ particles on $M = 8$ sites (corresponding to 16 single-particle states) with $V_0/J = 14$, $K/\hbar\omega = 4$, and two different interaction strengths. As expected, we can observe that, while the coupling to the $p$ band does not influence the heating time for low frequencies, it becomes dominant for large driving frequencies. For the two-band model the interplay between intraband and interband heating gives rise to a maximum of the heating time, $\tau_{\text{opt}}$, at some optimal intermediate driving frequency $\omega_{\text{opt}}$. For the larger interaction strength $\tau_{\text{opt}}$ is lower and occurs at a larger frequency.

To study the impact of interactions in more detail, we compare the frequency-dependent heating times for various interaction strengths $U_s/J_s$ in Fig. 5. The inset shows the optimal (maximum) heating time $\tau_{\text{opt}}$ (diamonds) and the corresponding optimal frequency $\omega_{\text{opt}}$ versus $U_s/J_s$. We observe a significant reduction of $\tau_{\text{opt}}$ combined with an upshift of $\omega_{\text{opt}}$, when increasing the interaction strength $U_s/J_s$ up to values of about 3. Both the shift of $\omega_{\text{opt}}$ and
the noticeable reduction of $\tau_{\text{opt}}$ for the single-band model (Fig. 3) suggest that increasing the interactions mainly enhances intraband heating, so that intraband heating becomes the dominant heating processes limiting $\tau$ up to larger values of $\omega$. For values of $U_s/J_s$ that are larger than 3 both $\tau_{\text{opt}}$ and $\omega_{\text{opt}}$ approximately saturate. We attribute this favorable behavior to the reaching of the strongly interacting regime $U_s/J_s \approx 2.5(U_s/J_s) \gg 1$ in the lowest band. Here the kinetic energy of the particles is not sufficient anymore to induce changes in the site occupations that are associated with a change of interaction energy (for an initial state without multiply occupied sites this regime corresponds to the hard-core boson limit). Once this regime is reached, the physics within the lowest band does not change much anymore, when the interactions are increased further, which is consistent with to the observed saturation. This argument holds until eventually for even stronger interactions, $U_{\text{sp}} \sim \Delta$, deviations due to interband coupling will make themselves felt.

In Fig. 6 we depict the lowest-band zero-quasimomentum occupation $n_0(t)$ in units of its initial value $n_0(0)$ at time $t \approx 40\hbar/J_s$. This time is chosen to be large compared to the tunneling time $\hbar/J_s$, which is the relevant time scale for experiments. It is plotted versus the interaction strength $U_s/J_s$ and the driving frequency $\hbar\omega/J_s$, where the low-frequency regime is shown in the left panel, while results for higher driving frequencies are given in the right panel. In the underlying simulations, we have considered a lattice depth of $V_0/E_R = 10$ and a driving strength of $K/\hbar\omega = 1.5$, which is smaller than the one used previously and does not induce a sign change of the effective tunneling matrix element $J_{\text{eff}}^{0} \approx 0.51J_s$. The latter implies that on the the level of the effective Hamiltonian, the quench induced when switching on the driving, does not correspond to an inversion of the effective dispersion relation, but rather to a reduction of the band width by a factor of one half. On the level of the time-averaged Hamiltonian (16), this rather mild quench will excite the system only weakly, so that the occupation $n_0(t)/n_0(0)$ will retain a rather large value also during the dynamics following the quench. Thus, a significant reduction of $n_0(t)/n_0(0)$ indicates unwanted driving-induced heating. Note also that (for fixed $K/\hbar\omega$) the ideal dynamics generated by $H_{\text{eff}}$, and thus also $n_0(t)/n_0(0)$, should be independent of the driving frequency. Therefore, also any frequency dependence of $n_0(t)/n_0(0)$ must be viewed as a deviation from the target dynamics generated by $H_{\text{eff}}$.

In Fig. 6 we find signatures of heating in the form of a significant reduction of $n_0(t)/n_0(0)$ in various regimes. In the regime of weak interactions $U_s/J_s \ll 1$, heating is visible both for too low frequencies, when $\hbar\omega \sim J_s$, as well as for too high frequencies, when $\hbar\omega \sim \Delta$ (with $\Delta/J_s \approx 250$ for the given lattice depth). When the interband interactions $U_s$ become larger than the interband tunneling $J_s$, low frequency heating sets in already for larger $\hbar\omega$, in accordance with condition (11). At the same time, we can also observe that interband heating at large frequencies is enhanced in the presence of interactions. For the chosen lattice depth of $V_0/E_R = 10$, we observe that strong interactions $U_s/J_s \gg 1$ lead to significant heating at any frequency.

The dependence of the heating time $\tau_{J_s}/\hbar$ on the lattice depth $V_0/E_R$ is investigated in detail in Fig. 7 where we plot the scaled heating time $\tau_{J_s}/\hbar$ versus $\hbar\omega/J_s$ for various values of $V_0/J_s$ and for $U_s/J_s = 5$ as well as $K/\hbar\omega = 4$. The inset shows $\tau_{\text{opt}}, J_s/\hbar$ and $\omega_{\text{opt}}, J_s/\hbar$ versus
V₀/E_R. We can observe that both τ_{opt}J_s/ℏ and ℏω_{opt}/J_s increase with the lattice depth. The main figure shows that this behavior is associated with a significant reduction of heating for large ℏω/J_s. Let us discuss this behavior in more detail.

First, we can notice that the intraband dynamics, described by the single-band Hamiltonian [12] and measured in the natural unit of the tunneling time ℏ/ℏ, is determined by the dimensionless ratios U_s/J_s, ℏω/J_s, and K/ℏω, which we kept fixed in our simulations when increasing the lattice depth V₀/E_R. This choice of fixed parameters is natural from the point of view of quantum simulation, where we wish to engineer the properties of the lowest band described by the approximate effective Hamiltonian [16]. It explains why for small ℏω/J_s, for which interband coupling is negligible, the dimensionless heating time τ_s/ℏ is hardly influenced by the lattice depth. This can be seen from the fact that all curves in Fig. 7 agree up to the point (∼ ℏω_{opt}/J_s), where τ_s/ℏ starts to be reduced by interband processes.

We can, moreover, observe in Fig. 7 that the interband heating, which is responsible for the reduction of τ_s/ℏ at large frequencies, is significantly reduced with increasing lattice depth. This behavior results from the interplay of various effects. On the one hand, with increasing lattice depth V₀/E_R the band separation Δ/E_R increases, whereas the interband coupling parameter η decreases (Fig. 1). Both effects tend to reduce interband heating. An additional and much stronger reduction of interband heating will, however, result from the exponential suppression of the tunneling parameter J_s with the square root of the lattice depth V₀/E_R (Fig. 1). Namely, since we keep the dimensionless ratio ℏω/J_s fixed (taking the point of view of quantum simulation, as explained in the previous paragraph), the number n_ph of photons (i.e. energy quanta ℏω) needed to overcome the band separation Δ, n_ph ≈ Δ/(ℏω), will strongly increase with the lattice depth. This, in turn, implies a very strong suppression of interband heating, since we expect an exponential suppression of interband transitions with n_ph [31, 32, 33].

The effects described in the previous paragraph explain a strong increase of the heating time τ with increasing lattice depth. However, from the point of view of quantum simulation, we have to compare the heating time to the relevant experimental time scale, given by the tunneling time ℏ/ℏ. This is why here we are always plotting the scaled heating time τ_s/ℏ. Therefore, when increasing the lattice depth, the expected strong increase of τ directly competes with the exponential increase of ℏ/J_s with the square root of the lattice depth. The results presented in Fig. 7 clearly show that the former effect wins over the latter one, so that, all in all, τ_s/ℏ is reduced when the lattice depth V₀/E_R is raised. We can, thus, see a noticeable increase of the optimal heating time τ_{opt}J_s/ℏ (shown in the inset of Fig. 7) with V₀/E_R.

While the results of Fig. 7 imply that driving-induced heating can effectively be reduced by raising the lattice depth, this possibility is limited by non-driving-induced heating processes, originating, e.g., from three-body collisions, scattering with background particles, or noise. Namely, the tunneling time, which increases with the lattice depth, has to remain short compared to the time scale τ_0 associated with such background heating. In turn, this means that by increasing τ_0 by reducing non-driving induced heating, the experimentalist can also reduce driving-induced heating. This is a major result of this article.

Let us, finally, also have a look at the dependence of the heating time on the driving strength. In Fig. 8 we plot τ_s/ℏ versus K/ℏω for a system with V₀/E_R = 14 and U_s/J_s = 5. We focus on values of K/ℏω that are interesting for Floquet engineering (i.e. that are large enough to achieve a significant modification of J_s^eff and not much larger than required for tuning J_s^eff to negative values). For the smallest considered driving strength of K/ℏω = 1 a narrow window of frequencies is found for which the heating time takes large values of more than 300 tunneling times. This window disappears for stronger driving. Note that we do not find a simple monotonous decrease of the heating time with respect to the driving strength. We attribute this observation to the non-monotonous behavior of the finite-frequency components of the time-dependent Hamiltonian [15] in the rotating frame (as well as of the corresponding two-band Hamiltonian). Namely, these terms, which describe heating processes beyond the rotating wave approximation [16] where the system exchanges m energy quanta ℏω, involve Bessel-function expressions J_m(K/ℏω) that depend in a non-monotonous way on the driving strength K/ℏω.

![FIG. 8. Heating time τ_s/ℏ versus driving frequency ℏω/J_s for the two-band model with different driving amplitudes K/ℏω, for N = 4, M = 8, V₀/E_R = 14, and U_s/J_s = 5. The inset shows the optimal (maximum) heating time τ_{opt} (diamonds) and the corresponding optimal frequency ℏω_{opt} versus K/ℏω.](image-url)
VI. CONCLUSIONS

In summary, we have investigated the conditions for Floquet engineering in optical lattices. In particular we were interested in the existence of a frequency window where both low-frequency intraband heating and high-frequency interband heating is suppressed on a time scale $\tau$ that is large compared to the tunneling time. Considering the concrete example of a small one-dimensional system of interacting bosons in a shaken optical lattice, we presented numerical results that show that such a frequency window exists for sufficiently deep lattices. The maximum ratio of heating and tunneling time, $\tau_{\text{opt}} J_s / \hbar$, (which is found for an optimal intermediate driving frequency $\omega_{\text{opt}}$) is found to increase with the lattice depth. This result, which is not obvious since also the tunneling time increases exponentially with the lattice depth, implies that we can reduce driving-induced heating, by simply ramping up the lattice depth. However, we have pointed out that this strategy is limited to lattice depths for which the tunneling time is still much smaller than the time scale $\tau_0$ for non-driving-induced background heating. Thus, the larger the time scale for such background heating, the more we can reduce also driving induced heating.

We have also found that ramping up the interaction strengths, driving-induced heating is significantly enhanced, until a saturation value is reached roughly when the ratio $U_s / J_s$ reaches values of 3. This saturation behavior is a promising result regarding the possibility of Floquet engineering of strongly correlated states of matter such as fractional Chern insulators \cite{50,51}.

An interesting direction for future work concerns the role of disorder. It has been argued that many-body localization can protect the driven system against unwanted heating associated with deviations from the high-frequency approximation \cite{54,55}. Roughly speaking, within the localization length, the system is not able to create excitations of a sufficiently large energy $\hbar \omega$. The mechanism is crucial also for the stabilization of discrete time crystals \cite{56,57}. However, disorder-induced localization cannot be expected to prevent the system also against unwanted heating associated with deviations from the low-frequency approximation. Unwanted resonant multi-photon excitations to states above the gap can still occur. It is an interesting question, in how far the corresponding heating rates are influenced by disorder-induced localization.

ACKNOWLEDGMENTS
