ABSTRACT Methicillin-resistant Staphylococcus aureus (MRSA) USA300 is a successful S. aureus clone in the United States and a common cause of skin and soft tissue infections (SSTIs). We performed whole-genome sequencing (WGS) of 146 USA300 MRSA isolates from SSTIs and colonization cultures obtained from an investigation conducted from 2008 to 2010 in Chicago and Los Angeles households that included an index case with an S. aureus SSTI. Identifying unique single nucleotide polymorphisms (SNPs) and analyzing whole-genome phylogeny, we characterized isolates to understand transmission dynamics, genetic relatedness, and microevolution of USA300 MRSA within the households. We also compared the 146 USA300 MRSA isolates from our study with the previously published genome sequences of the USA300 MRSA isolates from San Diego (n = 35) and New York City (n = 277). We found little genetic variation within the USA300 MRSA household isolates from Los Angeles (mean number of SNPs ± standard deviation, 17.6 ± 35; π nucleotide diversity, 3.1 x 10^-5) or from Chicago (mean number of SNPs ± standard deviation, 12 ± 19; π nucleotide diversity, 3.1 x 10^-5). The isolates within a household clustered into closely related monophyletic groups, suggesting the introduction into and transmission within each household of a single common USA300 ancestral strain. From a Bayesian evolutionary reconstruction, we inferred that USA300 persisted within households for 2.33 to 8.35 years prior to sampling. We also noted that fluoroquinolone-resistant USA300 clones emerged around 1995 and were more widespread in Los Angeles and New York City than in Chicago. Our findings strongly suggest that unique USA300 MRSA isolates are transmitted within households that contain an individual with an SSTI. Decolonization of household members may be a critical component of prevention programs to control USA300 MRSA spread in the United States.

IMPORTANCE USA300, a virulent and easily transmissible strain of methicillin-resistant Staphylococcus aureus (MRSA), is the predominant community-associated MRSA clone in the United States. It most commonly causes skin infections but also causes necrotizing pneumonia and endocarditis. Strategies to limit the spread of MRSA in the community can only be effective if we understand the most common sources of transmission and the microevolutionary processes that provide a fitness advantage to MRSA. We performed a whole-genome sequence comparison of 146 USA300 MRSA isolates from Chicago and Los Angeles. We show that households represent a frequent site of transmission and a long-term reservoir of USA300 strains; individuals within households transmit the same USA300 strain among themselves. Our study also reveals that a large proportion of the USA300 isolates sequenced are resistant to fluoroquinolone antibiotics. The significance of this study is that if households serve as long-term reservoirs of USA300, household MRSA eradication programs may result in a uniquely effective control method.

Staphylococcus aureus is the most common cause of human skin and soft tissue infections (SSTIs) and is also a common cause of osteomyelitis, endocarditis, and pneumonia (1). Methicillin-resistant S. aureus (MRSA) strains are resistant to all β-lactam antibiotics, with the exception of new cephalosporins, and have posed therapeutic challenges since their first description more than 50 years ago (2). In the 1990s, an epidemic of MRSA infections in the United States began outside health care facilities (3). With this shift in epidemiology, the majority of patients who seek care for S. aureus SSTIs in United States emergency departments (4), jails (5), large medical centers (6), and community primary-care offices (7) are infected with MRSA.

By 2004, nearly all of the MRSA isolates from community-associated SSTIs in the United States (>97%) had a common pulsed-field gel electrophoresis (PFGE) type, known as USA300 (6, 8). In these strains, the Panton-Valentine leukocidin (PVL) toxin genes (lukS-PV and lukF-PV), the arginine catabolic mobile element (ACME), and staphylococcal cassette chromosome mec
(SCCmec) type IV were almost uniformly present. In contrast, these characteristics were rarely found in health care-associated MRSA (HA-MRSA) strains (9). USA300 MRSA (referred to here as USA300), in addition to causing SSTIs, has emerged as a common cause of invasive infections (10). The success of USA300 in both community and health care settings has been attributed to overexpression of the global transcriptional regulator agr and sae, leading to increased expression of toxin genes, including PVL (11–13). Also in USA300, the presence of ACME likely enhances the survival of MRSA on the skin (14).

A critical reservoir of USA300, as for all S. aureus strains, is asymptomatic colonization of the human body. Studies have been performed among household contacts of patients with S. aureus infections to assess the frequency of asymptomatic colonization (15, 16). S. aureus colonization of more than one individual in the household of a patient already infected has been identified, but until recently, studies have either not assessed the genetic relatedness of strains or have used sequence-based techniques with limited discriminatory power (17).

Whole-genome sequencing (WGS) has come into general use in bacterial epidemiological studies as it offers the ultimate level of sensitivity in the genetic discrimination of closely related strains and the identification of genetic markers associated with virulence and antibiotic resistance (18–20). We set out to determine if WGS could identify single nucleotide polymorphisms (SNPs) among USA300 isolates that would cluster by household or city of origin. Using a large number of isolates collected in two different geographic regions, we provide strong evidence that USA300 spreads within households and persists for a period of several years. Furthermore, we show that a large number of the USA300 isolates, predominantly from California, had acquired mutations associated with fluoroquinolone resistance, whereas the prevalence of resistance remained low in Chicago. This study reveals the microevolutionary processes that are shaping the USA300 epidemic.

RESULTS

Long-term persistence of USA300 MRSA in households. We sequenced 146 USA300 isolates to an ~200X median depth of coverage per strain. The strains were reconfirmed as belonging to sequence type 8 (ST8) from the WGS data by using the Short Read Sequence Typing (SRST) tool (21). The 2,203,292-bp core nucleotide sequence (of the 2.9-Mb genome) common to all USA300 isolates extracted from the progressiveMauve alignment was used for a Bayesian coalescent analysis implemented in BEAST (Bayesian evolutionary analysis by sampling trees) to derive estimated dates for the common ancestors of the strains. Using a strict molecular clock and a Bayesian skyline demographic model, we estimated an average mutation rate of 1.25 \( \times 10^{-6} \) (95% confidence interval, 1.02 \( \times 10^{-6} \) to 1.52 \( \times 10^{-6} \)) mutations per site per year, similar to that reported previously in USA300 and other S. aureus genetic types (17, 22–25). Uhlemann et al. reported a mutation rate of 1.22 \( \times 10^{-6} \) (95% confidence interval, 6.04 \( \times 10^{-7} \) to 1.86 \( \times 10^{-6} \)) mutations per site per year in the USA300 isolates analyzed from the New York City (17). Similarly, a mean nucleotide substitution rate of 2.0 \( \times 10^{-6} \) (95% confidence interval, 1.2 \( \times 10^{-6} \) to 2.9 \( \times 10^{-6} \)) per site per year in ST225 S. aureus strains of Central Europe was estimated (22). The average estimate of the time to the most recent common ancestor (TMRCA) of the USA300 isolates indicates a divergence at around 1993, consistent with observations of the start of the epidemic of community-associated MRSA (CA-MRSA) infections caused by this strain type in the United States (26). In addition, our analysis revealed that the fluoroquinolone-resistant strains emerged in the mid-1990s (Fig. 1). The BEAST analysis demonstrated a range of mean TMRCAs based on the final date of isolation of bacteria in 2010 from households of 2.33 years (household 9131) to 8.35 years (household 8113) (see Table S1 in the supplemental material). However, the 95% confidence intervals for these dates fail to overlap only for the two isolates at the maximum and minimum ends of the scale. We also constructed a well-supported root-to-tip regression plot of the date of isolation of these strains and increased genetic diversity by using Path-O-Gen (correlation coefficient, 0.351; r² = 0.123) (see Fig. S1 in the supplemental material). The root-to-tip regression analysis suggested a rate estimate (1.21 \( \times 10^{-6} \) per site per year) and TMRCA of the USA300 isolates very similar to those obtained in the Bayesian coalescent analysis.

Continuous reshaping of the USA300 pangenome. We investigated the pangenome composition of the 146 USA300 draft sequenced strains and 49 completely sequenced genomes of S. aureus available in the National Center for Biotechnology Information (NCBI) refSeq database (see Table S2 in the supplemental material). Unsupervised hierarchal clustering based on patterns of the presence or absence of gene families (27) grouped all of the USA300 strains in the same clade (see Fig. S2 in the supplemental material). Twelve strains from Chicago household 9033 were missing the ACME cassette (Fig. 2). The position of the ACME-negative strains in the phylogeny suggested the deletion of a preexisting island. Interestingly, the index infection isolate of this household (strain 120381) is from a phylogenetically distinct ACME-positive lineage. This genotype was not subsequently detected in household 9033 at 3 or 6 months. Our study design
precluded an analysis of the loss or gain of PVL genes because the presence of the PVL genes was a criterion for isolate inclusion in this study.

There was evidence that USA300 clones, when persisting in households, continued to acquire extraneous DNA by horizontal gene transfer (HGT) and recombination. A few isolates acquired new genes on phages (e.g., isolate 119700 in household 8012) compared with others within the same household. This event could only have occurred after the strain entered the household, and thus, the DNA must have originated from coresident Staphylococcus species (28) on the colonized human host. Likewise, there are at least two SNP patterns that are best explained by an exchange of short segments of DNA through homologous recombination with a non-USA300 S. aureus isolate. In strain 119720, from household 8182 in Los Angeles, there are five SNPs in a short intergenic region (coordinates 1996070 to 1996129 bp of the TCH1516 genome) that match the ancestral S. aureus genome rather than the typical USA300 genome. This suggests that a homologous recombination event may have taken place prior to the introduction of USA300 into household 8182.

**Clustering of USA300 within households.** To investigate the clustering of strains within households, we constructed a minimum spanning tree (MST) based on an alignment matrix of 1,629 core protein clusters (1,335,849 bp) of USA300 as determined by OrthoMCL. Similar to BEAST phylogeny, strains in the MST were split into two clades (Fig. 3). Also, 18 of 21 households contained USA300 isolates clustered into closely related monophyletic groups, which suggested the introduction into each household of a single USA300 ancestor strain. The index infection isolate haplotype was the connection of the household-specific branch to the majority of the strains in the MST (12 out of 21 households, $P = 1.0$, Fisher’s exact test). This suggests that in many households the index cases’ infection isolates were not responsible for the introduction of USA300 into these households; instead, the infecting isolate was derived from isolates that were already present in the household.

In addition, households could generally be connected to the root of the phylogenetic tree without passing through another household. This finding supports the hypothesis that, for the samples in this study, transmission occurred primarily within the households after a single introduction and does not support the alternative explanation that there were frequent or repeated introductions of USA300 from another reservoir outside the household. Overall, the levels of genetic diversity within the Los Angeles...
and Chicago isolates were similar, with medians of six (mean and standard deviation of 17.6 ± 35 [range, 0 to 199]) and five (mean and standard deviation of 12 ± 19 [range, 0 to 102]) SNPs per household, respectively (see Fig. S3 and Table S1 in the supplemental material). The nucleotide diversity (π, the average number of nucleotide differences per site between two sequences) was also the same (π = 3.1 × 10⁻⁵) in both Los Angeles and Chicago isolates and was similar to the diversity reported for S. aureus isolates of the ST225 genetic background from Central Europe (22). The theta (θ) diversities of Chicago and Los Angeles isolates, respectively, were estimated to be 5.4 × 10⁻⁵ and 7.1 × 10⁻⁵. A core protein alignment-based maximum-likelihood (ML) phylogeny resulted in similar clustering of the isolates within the households studied (see Fig. S4 in the supplemental material).

Evolution of fluoroquinolone-resistant USA300. To identify genetic changes driving the clustering of strains within the two larger clades, we estimated genome-wide Weir and Cockerham’s $F_{ST}$ (genetic differentiation) between the bacterial populations identified in Los Angeles and Chicago. We found eight SNPs (three nonsynonymous, two synonymous, and three intergenic) that were highly differentiated between Chicago and Los Angeles isolates (Fig. 4). Two of the three nonsynonymous SNPs within the gyrase A (gyrA S84L) and topoisomerase IV (grlA S80Y) genes were associated with fluoroquinolone resistance in S. aureus (17, 29) and several other bacterial species (30–32). The third nonsynonymous SNP was in a poorly characterized gene called whiA (whiA D17E) located close to the essential walKR cell wall two-component signal transduction system.

Phenotypic ciprofloxacin resistance segregated with the presence of the gyrA and grlA SNPs. All of the isolates from the households in clade II harbored the mutations gyrA S84L and grlA S80Y, conferring fluoroquinolone resistance, whereas those in clade I were fluoroquinolone susceptible (Fig. 1 and 3; Table 1). With the exception of one household (no. 9141), fluoroquinolone resistance also clustered by household; all of the isolates within a household were either susceptible or resistant. The four
fluoroquinolone-resistant strains in household 9141 segregated with clade II, while only one susceptible strain segregated with clade I (Fig. 3). In an example of parallel evolution, the same two mutations were observed in EMRSA-15, an epidemic healthcare-associated ST22 strain that emerged in the United Kingdom in the 1980s (25). Fluoroquinolone resistance has also been associated with the rapid intercontinental spread of another Gram-positive pathogen, \textit{Clostridium difficile} (32).

Fluoroquinolone resistance in USA300 is not geographically constrained. A high-resolution ML phylogeny based on core genome alignment of 460 USA300 strains from San Diego (23), Los Angeles (this study), Chicago (this study), and New York City (17) was constructed in REALPHY (33). As shown in Fig. 5, the isolates with and without fluoroquinolone resistance-conferring mutations \textit{gyrA} S84L and \textit{grlA} S80Y were grouped into two clades (Fig. 5). Fluoroquinolone-resistant USA300 strains, however, were more widespread in San Diego (28/35, 80.0%), Los Angeles (59/70, 84.2%), and New York (186/277, 67.1%) than in Chicago (23/75, 30.6%) ($P < 0.0001$ for each comparison).

**DISCUSSION**

Utilizing WGS of USA300 isolates from households in two cities, Chicago and Los Angeles, we have demonstrated that households serve as major sites of MRSA transmission. A recent study by Uhlemann et al. observed similar results in household isolates from New York City (17). With time, strains in the households that we studied acquired a small number of point mutations and DNA from HGT from other bacteria (likely \textit{Staphylococcus} species or other close relatives of \textit{S. aureus}). It would be useful in the context of USA300 epidemiology to consider whether the virulence potential of strains decreases over time in a small human population. We found no genome-wide patterns of nucleotide substitution or HGT to distinguish strains colonizing individuals from those causing infections, unlike in other studies (23, 34). There were few SNPs in Los Angeles and Chicago household isolates, similar to findings in earlier studies, suggesting a recent clonal expansion and diversification of USA300 clones (17, 23, 35). We also observed that the USA300 isolates from different regions of the United States belonged to the same clade of the whole-genome ML phylogenetic tree, suggesting frequent migration of strains between geographical regions.

Importantly, we showed in this study that USA300 clonal lineages persisted within households for about 2 to 8 years before a

mutations in the nomes in REALPHY. The fluoroquinolone-susceptible isolates (i.e., with no
structed with the 2,104,213-bp core sequence alignment of these isolate ge-
strains (Newman and COL) included as outgroups. The ML tree was con-

man (indicated by orange branch tips. Three isolates indicated by purple tips had
isolates had a different set of mutations (80Y and grlA 84L). These find-
ings echo other recent North American studies (17, 38). We cannot ascertain at this stage whether clade II is replacing the older fluoroquinolone-sensitive lineage or what the significance of the higher frequency of fluoroquinolone resistance in Los Angeles than in Chicago is. Unlike ST22 (EMRSA-15) (25), another clade that has acquired and frequently exhibits fluoroquinolone resis-
tance and is primarily HA-MRSA, USA300 is primarily CA-MRSA
(39). The fluoroquinolone-resistant strains may have been selected for by
antibiotic treatment for other conditions. This raises the question
whether mutations, over time, lead to enhanced human coloniza-
tion or to enhancement of the potential of a USA300 strain to
cause an infection.

We believe the next step to answering the questions raised in
this work is a longitudinal evaluation of the USA300 isolates
within households to examine the patterns of person-to person
transmission, the persistence of fluoroquinolone resistance, and
whether mutations, over time, lead to enhanced human coloniza-
tion or to enhancement of the potential of a USA300 strain to
cause an infection.

MATERIALS AND METHODS

Household survey and strain collection. In our household contact study, 350 evaluable index patients with SSTIs were enrolled between August 2008 and June 2010 at the University of Chicago Medical Center (n = 177) or at the Harbor-UCLA Medical Center (n = 173). Details of this study have been described previously (16). Each member of the household of each consenting index patient was visited on three occasions, <21 days after the treatment of the SSTI (baseline) and 3 and 6 months after the baseline visit. At each visit, the index patient and each household contact

symptomatic patient was admitted to a hospital and continued for at least another year afterward. This could be caused by a combi-
nation of long-term asymptomatic human carriage (36) and/or frequent reinfec-
tions from other household members, pets, or fomites. We need to understand how MRSA persists (the reasons may be different in different households) to design decolonization strategies and public health programs aimed at controlling the spread of USA300. Interventions may need to address all of the symptomatically infected and asymptotically colonized indi-
viduals in a household.

We found that households were common sites of USA300
were tested for *S. aureus* colonization by cultivating samples from the nares, the oropharynx, and the inguinal region. All of the *S. aureus* isolates obtained from the index SSI (the index infection isolate) and from colonization cultures from index patients and household contacts from all three household visits underwent genotyping by multilocus sequence typing (MLST), SCCmec typing, and assessment for the presence of PVL genes. Isolates were considered to be USA300 if they were of ST8 and carried SCCmec type IV and the PVL genes (16), as shown in a previous validation study (40). Susceptibility to ciprofloxacin was tested by the broth microdilution method as recommended by the Clinical and Laboratory Standards Institute (41).

Among 1,162 persons enrolled (350 index patients and 812 household members), *S. aureus* colonized 40% (135/350) of the index patients and 30% (405/812) of their household contacts at one or more sites. Factors independently associated (*P* < 0.05) with the index infection isolate strain type being present colonizing a household contact were recent skin infection in the contact, recent cephalaxin use, and USA300 genetic background of the index infection isolate (see Table S3 in the supplemental material) (16). USA300 was the predominant *S. aureus* type identified among the infecting (53%) and colonizing (29%) isolates. We randomly selected 21 households, 12 from Los Angeles and 9 from Chicago (a total of 146 isolates) for WGS that met the following criteria. (i) The index infection isolate was USA300, and (ii) at least two household members (one of whom could be the index patient) were colonized with USA300 at one or more body sites at the baseline visit (see Table S3 in the supplemental material). Additional information on recruitment has been previously published (16).

WGS, SNP calling, genome assembly, and annotation. DNA was extracted from each isolate with the Qiagen genome preparation kit according to the manufacturer’s protocol. Sequencing libraries were prepared with 1 to 2 μg of DNA by following the standard Illumina protocols and chemistry and paired-end sequencing was performed on the Illumina HiSeq 2000 platform (Illumina Inc., San Diego, CA), generating 100-bp sequence reads. The MLST genetic background of the isolates was reconfirmed from the WGS data by using the SRST tool (21). To minimize errors and artifacts in the downstream analyses, sequence reads were preprocessed with PRINSEQ (version 0.20.3) (42). The preprocessing of the reads involved two sequential steps. In the first step, we simply discarded any reads with two or more N’s or a mean Phred quality score of <20. In the second step, bases with low Phred quality scores (≤19) were trimmed from the 3’ end, and if the length of the trimmed reads fell below 70 bp, they were removed from further analysis. The resulting high-quality reads were aligned against the *S. aureus* USA300 TCH1516 reference genome (GenBank accession number NC_010079; 2,872,915-bp length) with the Bowe-Wheeler Aligner (version 0.7.2) with a mismatch penalty of 3 and a gap open penalty of 5 (43). The programs SAMtools and Picard Tools were used to format and reformat the intermediate-alignment files, and variant SNPs and insertions–deletions (indels) were identified with the Genome Analysis Toolkit UnifiedGenotyper (44, 45). We considered only those variant positions that were covered by at least 10 reads, and 90% or more sequence reads supported mutation (an allele different from the TCH1516 reference genome). We also excluded the variants if they were in the homopolymer tract regions or were ambiguous in or missing from any of the isolates.

Velvet (version 1.2.06) was used for *de novo* genome assembly (46). The assembled contigs larger than 200 bp were ordered and converted into a single pseudocontig with Abacas (47) and finally annotated with the bacterial genome annotation tool Prokka (48).

Orthologous gene clustering, pangenome analysis, and core genome phylogeny. The predicted proteins from each isolate were categorized into orthologous clusters by OrthoMCL (with the option --e value for BLAST alignments set at 1e-05 and --c set at 75%) as implemented in GET_HOMOLOGUES (27, 49, 50). The pangenome matrix (presence and absence of genes/proteins) produced from the OrthoMCL step was used for hierarchical gene clustering analysis with the R heatmap2 function (51). Deletions of ACME or any other large region of the genome were examined and visualized with the CGView comparison tool (CCT) (52), which uses all-versus-all BLAST to compare the genomes and presents the homology as a circular map. The 1,629 core protein clusters identified in 148 USA300 isolates (proteins present in all 148 isolates), which included the two reference strains TCH1516 and FPR3757, by OrthoMCL were individually aligned with Muscle (53), edited in trimAl (54) to eliminate positions containing gaps and poorly aligned regions, and finally concatenated to generate a single alignment (445,283 amino acids) of the core protein clusters. The nucleotide sequence alignments corresponding to each core protein cluster were retrieved with PAL2NAL (55) and concatenated to create a nucleotide alignment matrix (1,335,849 bp) of core gene clusters.

Phylogenetic analysis with the above core protein and core gene alignment matrices was performed to investigate genetic relationships among household strains by two different methods. An MST based on the alignment matrix of core gene clusters was generated in a Bioconductor library Rgraphviz (version 2.6.0) (56). ML trees based on the core gene and core protein alignment matrices were constructed in RAXML (version 7.0.4) (57) under GTR+gamma and HVRV substitution models, respectively. The best-fit nucleotide and amino acid substitution models, respectively, were determined with jModelTest (v.0.1.1) (58, 59) and ProtTest (60) on the basis of the Akaike information criterion score and the number of estimated parameters. The node support of the ML tree was assessed by the nonparametric bootstrapping method with 200 replicates.

**Estimation of *F*<sub>S</sub>.** To identify the SNP loci highly differentiated between Los Angeles and Chicago USA300 MRSA isolates, the Weir and Cockerman genetic statistics (*F*<sub>S</sub>, 61) across all 1,585 SNP loci identified in USA300 isolates with reference to the TCH1516 USA300 genome (obtained at the SNP calling step as described above) was estimated with the divelRity R package (version 1.7.6) (62).

**Estimation of substitution rate and duration of presence within households.** The rate of substitution within the USA300 genome and age of infection within each household were estimated with BEAST, version 2.0.2 (63). For this analysis, we aligned 146 USA300 draft genomes produced in this study along with two completed genomes of USA300 strains TCH1516 and FPR3757 with the progressiveMauve algorithm of Mauve (64). The core alignment blocks longer than 500 bp, shared by all of the genomes (locally collinear blocks) were concatenated to produce a 2,203,292-bp alignment matrix. An ML tree was constructed with this alignment under the GTR+gamma substitution model in RAXML as described above. Linear regression analysis was performed to assess the relationship between root-to-tip branch length and the date of isolation of the isolates in Path-O-Gen (http://tree.bio.ed.ac.uk/software/pathogen/).

Three independent runs of BEAST, each with 300 million Markov chain Monte Carlo (MCMC) generations, sampling every 10,000 generations were performed with the following settings: a strict molecular clock, the HKY model of nucleotide substitution, and a Bayesian skyline coalescent, as used by Uhlemann et al. (17) and Nübel et al. (22). The date of isolation of the USA300 strains for this analysis were specified in day, month, and year. The log files resulting from all three runs were analyzed to assess convergence by checking the effective sample sizes (ESSs) of different parameters in Tracer (version 1.5). After confirming that all three runs had converged on the same posterior distribution in the MCMC run with almost identical marginal density distributions and all of the parameters had an ESS of >200, they were combined in LogCombiner (version 2.0.2), discarding the first 25% of the MCMC generations as a burn-in phase. A single maximum clade credibility tree was summarized in TreeAnnotator (version 2.0.9) and visualized in FigTree (version 1.4.0). We also conducted another BEAST run by using a strict molecular clock, the HKY nucleotide substitution model, and a constant size coalescent to rule out the impact of demographic models on our estimates (see Table S1 in the supplemental material).

**Phylogenetic structures of all available USA300 genomes.** In order to investigate the high-resolution phylogenetic structures of all of the avail-
able USA300 isolates sequenced to date, we reanalyzed 146 strains sequenced in this study along with 321 previously published sequences of USA300 isolates from San Diego, CA \((n = 35)\) (23), and New York, NY \((n = 277)\) (17). In addition, we included the completed genomes of USA300 strains TCH1516 and EPR3757. An ML phylogeny of these 460 USA300 isolates was constructed on the basis of their core genome alignment \((2,104,213 \text{ bp})\) with PhyML as implemented in REALPHY (33).

**Nucleotide sequence accession numbers.** The raw sequence reads analyzed in this study have been deposited in the NCBI Sequence Read Archive database under accession number SRP039020. The GenBank accession numbers of all of the completed \(S. aureus\) genomes used in this study are listed in Table S2 in the supplemental material.

**SUPPLEMENTAL MATERIAL**

**ACKNOWLEDGMENTS**

This work was supported by National Institutes of Health grants AI091827 to T.D.R., AI067584-01 to R.S.D., and AI095361-01 to M.Z.D. The support of the Emory Genome Center (EGC) is gratefully acknowledged. Equipment used by EGC was funded by the Atlanta Clinical and Translational Sciences Institute, the Department of Human Genetics, and the School of Medicine. We thank Jessica Peterson for assistance and support during this study. We also thank Julia Sith for assistance with genotyping and organization of isolates.
