(Dated: March 23, 2022)

In a high mobility two-dimensional electron system in Si, near the critical density, $n_c = 0.32 \times 10^{11}$ cm$^{-2}$, of the apparent metal-to-insulator transition, the conductivity displays a linear temperature ($T$) dependence around the Fermi temperature. When $\sigma_0$, the extrapolated $T = 0$ conductivity from the linear $T$-dependence, is plotted as a function of density, two regimes with different $\sigma_0(n)$ relations are seen, suggestive of two different phases. Interestingly, a sharp transition between these two regimes coincides with $n_c$, and $\sigma_0$ of the transition is $\sim e^2/h$, the quantum conductance, per square. Toward $T = 0$, the data deviate from linear $\sigma(T)$ relation and we discuss the possible percolation type of transition in our Si sample.

PACS numbers: 72.20.-i, 71.30.+h

The nature of the ground state of an interacting two-dimensional electron system (2DES) in the presence of disorder is a long-standing problem in condensed matter physics. More than a decade ago, an apparent 2D metal-to-insulator transition (MIT) was first reported as the density of a Si MOSFET is reduced through a characteristic density $n_c$. Despite much research effort later in the field, there remain several unsettled fundamental questions. For example, metallic behavior is observed for density $n > n_c$. Does this metallic-like state persist down to $T = 0$ and thus represent a true 2D metal? Besides, the 2DES eventually becomes insulating as ever-decreasing densities. Is this phenomenon related to a novel phase transition due to strong electron-electron (e-e) interactions, or is it a mundane crossover just due to a complex combination of many well-understood physical mechanisms?

In an earlier publication, we reported the observation of the metallic behavior and the apparent 2D MIT in a high mobility Si quantum well. The high-density metallic-like state and its response to an in-plane magnetic field are emphasized in that paper. In this communication, we focus on the transport properties for densities close to the transition. Here, the conductivity displays a linear temperature dependence near $T = T_F$ (the Fermi temperature) and the slope is the same for all different densities around $n_c$. When the extrapolated $T = 0$ conductivity, $\sigma_0$, of this $T$-dependence is plotted as a function of density, two regimes with linear $\sigma_0$ vs $n$ relations are readily seen. Interestingly, these two $\sigma_0(n)$ lines cross each other exactly at $n_c$ and $\sigma_0$ at the crossing coincides with the quantum conductance, $e^2/h$, per square. At low temperatures, $T < < T_F$, the measured $\sigma(T)$ deviates from the linear $T$-dependence. We discuss the low-$T$ behavior of our data within the percolation model.

The experiments were performed on the 2DES in an $n$-type Si quantum well confined in a Si$_{0.75}$Ge$_{0.25}$/Si/Si$_{0.75}$Ge$_{0.25}$ heterostructure. The 2D electron density is tuned continuously by applying a front gate voltage to our field-effect transistor device. Details of the growth and the sample structure can be found in Ref. [6]. Standard low-frequency ($\sim 7$Hz) lock-in techniques were used to measure the 2D resistivity $\rho$. At $T \sim 300$mK and zero gate voltage, the 2DES has a density $n = 1.45 \times 10^{11}$cm$^{-2}$ and mobility $\mu = 190,000$cm$^2$/Vs.

In Fig. 1(a), we reproduce selected $T$-dependence data $\rho(T)$ from our previous paper. Toward the $T = 0$ limit, the apparent 2D MIT is clearly seen at the critical density $n_c = 0.32 \times 10^{11}$cm$^{-2}$, where $d\rho/dT \sim 0$ for $T < 1$K. The insulating behavior, $d\rho/dT < 0$, is observed for densities below $n_c$ and metallic-like behavior, $d\rho/dT > 0$, above $n_c$. For further insights to the 2D MIT, we now focus on the data around $n_c$ and plot the inverse resistivity, or conductivity $\sigma$, as a function of temperature in the density range of $0.27 \times 10^{11} < n < 0.38 \times 10^{11}$cm$^{-2}$ in Fig. 1(b). In the low-$T$ limit, the MIT is again observed in that $d\sigma/dT$ changes sign as $n$ changes through $n_c$. At high temperatures when $T$ approaches the Fermi temperature $T_F$, marked as short lines for each density, however, all $\sigma(T)$ curves show roughly a linear $T$-dependence and bends slightly downward for $T$ sufficiently higher than $T_F$.

To illustrate this linear $\sigma(T)$ relation around $T = T_F$, we show the linear fits, $\sigma(T) = \sigma_0 + \gamma T$, for several densities, where $\gamma$ is the slope and $\sigma_0$ the linear extrapolation to $T = 0$. In the inset of Fig. 2, $\gamma$ is plotted as a function of the density. It is nearly constant, $\sim 0.43 \pm 0.01 e^2/h$ per Kelvin, for $n < 0.38 \times 10^{11}$cm$^{-2}$ and then rapidly decreases for higher densities. We plot $\sigma_0$ vs $n$ in Fig. 2 and two regimes with different linear $\sigma_0(n)$ relations are readily identified. On the low-density insulating side, $\sigma_0$ increases as increasing density at a rate of $11 e^2/h$.
FIG. 1: (a) Selected data of $\rho(T)$ in a high quality Si quantum well reproduced from Fig. 1 in Ref. [5]. (b) $\sigma(T)$ in the vicinity of the critical density. The electron densities, from bottom to top, are 0.268, 0.282, 0.296, 0.303, 0.318, 0.322, 0.324, 0.328, 0.336, 0.344, 0.352, 0.358, 0.365, 0.374, and 0.380, in units of $10^{11}$ cm$^{-2}$, respectively. The short, vertical lines mark the Fermi energy at each density. The lines on some curves are the linear fits around $T = T_F$.

per $10^{11}$ cm$^{-2}$. The slope roughly doubles to $26 e^2/h$ per $10^{11}$ cm$^{-2}$ on the high-density side. Strikingly, the $\sigma_0(n)$ data show a sharp bend at the crossing of the two straight lines at $n = 0.32 \times 10^{11}$ cm$^{-2}$, which coincides with $n_c$ of the 2D MIT. And $\sigma_0$ at this density exactly equals the quantum conductance, $e^2/h$, per square. For both regimes, we extrapolate the linear $\sigma_0(n)$ to zero conductivity at $n_1 = 0.23 \times 10^{11}$ cm$^{-2}$ on the low-density side and $n_2 = 0.28 \times 10^{11}$ cm$^{-2}$ on the high-density side.

Linear $\sigma(T)$ relation has been observed before in p-type GaAs samples [7,8]. There, $\gamma = \sigma_0(n) / T_F$ at $T_F < 2.5 K$, compared to the much smaller number, $\sim 0.43 e^2/h$ per Kelvin, in our Si quantum well sample. This order of magnitude difference might be related to the different Fermi temperatures in these two systems. As will be shown below, $\sigma_0(n) / T_F$ at $T_F < 2.5 K$ is an order of 10 larger than that ($\sim 0.1$ to 0.4 K) in the p-GaAs samples. As a result, $\sigma_0(n) / T_F$ in Si is expected to be $\sim 10$ times smaller than in p-GaAs.

Theoretically, the linear $\sigma(T)$ in the high temperature regime has also been addressed by several models. Das Sarma and Hwang [4] calculated the temperature dependence of $\sigma$ within a classical model of the screened charged impurity scattering. For $T >> T_F$, they observed that $\sigma(T) \sim T / T_F \propto T$, consistent with our experimental observation. Besides the screening model, the micro-emulsion model proposed by Spivak and Kivelson [10] can also explain the linear $\sigma(T)$ at high temperatures. In this model, near $n_c$, the ground state of the 2DES consists of an electron liquid with Wigner crystal inclusions on the metallic side, and Wigner solid with liquid inclusions on the insulating side. At high temperatures, Wigner crystal droplets melt and the system behaves classically. In analogy to the physics of $^3$He near the crystallization pressure [10], the viscosity of the electron liquid, which is directly proportional to the resistivity, is inversely proportional to $T$, resulting in a linear $\sigma(T)$, again consistent with our observation [11].

Quantitatively, however, neither of the two above models can explain the experimental observation that $d\sigma/dT$ is nearly independent of the electron density around $n_c$. Under the temperature dependent screening model, $d\sigma/dT$ is proportional to $1/T_F$ or $n^{-1}$ [4]. As a result, the slope should decrease by a factor of $\sim 1.5$ when the 2DES density increases from 0.27 to $0.38 \times 10^{11}$ cm$^{-2}$. On the other hand, the micro-emulsion model shows $d\sigma/dT \sim n^2$ [10]. Consequently, in the same density range, the slope should change roughly by a factor of 2. In contrast, $d\sigma/dT$ is nearly constant and $\sim 0.43 \pm 0.01 e^2/h$ per Kelvin in our measurements. So far, it is not known what is responsible for this inconsistency between our experimental result and the theoretical predictions.

Having discussed the linear T-dependence of the data, we need to address some puzzling aspects of the overall results. First, the examined specimen has very high electron mobility and the $n_c$ of the 2D MIT is by far the lowest among all the Si-based samples. The e-e interaction parameter $r_s$ at the transition density is $\sim 10$, i.e., the Coulomb energy $E_c$ exceeds the Fermi energy $E_F$ by a factor of 20, after taking into account the two-fold valley...
degeneracy in (001) Si 2DES. Consequently, even though the system behaves classically for \( T \sim T_F \), the 2DES is still strongly correlated since \( E_c \) is the dominant energy scale here. Second, if the high-T physics underlying the linear \( \sigma(T) \) behavior persists to the \( T = 0 \) limit, our \( \sigma_0(n) \) data show two distinct regimes, possibly suggesting two different electronic phases below and above \( n_c \). The transition between the two density regimes is sharp, and occurs almost exactly at \( n_c \). \( \sigma_0 \) at this transition point is very close to \( e^2/h \), the unit of quantum conductance, per square, manifesting a possible quantum nature of this transition. The reduction of the rate, \( d\sigma_0/dn \), of the density dependence, from \( \sim 26e^2/h \) per 10\(^{11}\) cm\(^{-2}\) above \( n_c \) to \( \sim 11e^2/h \) per 10\(^{11}\) cm\(^{-2}\) below \( n_c \), clearly indicates that in the low-density regime the 2D electrons are less likely to become localized by reducing the 2DES density. Considering the large \( r_s \) at \( n_c \), one might speculate that strong e-e interactions help to prevent electrons from being localized at low densities. Indeed, in a recent publication \[12\], Shi and Xie showed that, with e-e interactions taken into account, the 2DES becomes less localized compared to a non-interacting system at the same density. However, the appearance of two density regimes is still unexplained because a smooth evolution should be expected from their calculations.

We now turn to the low-T limit of the measured \( \sigma(T) \) in Fig. 1(b). Instead of following the trend from high temperatures, the conductivity deviates from the linear T-dependence toward the \( T = 0 \) ground state configuration. It has long been suggested that the apparent MIT observed here might be of a density inhomogeneity effect, and belongs to a general class of 2D percolation problem \[13, 14\]. In this picture, at very low densities, the 2DES is macroscopically inhomogeneous and first forms isolated puddles by occupying the low potential “valleys”. As \( n \) increases, the area of the electron puddles increases and at the percolation threshold density \( n_p \), some puddles are connected, giving rise to a conducting path throughout the sample. Experimentally, this percolation-type 2D MIT is supported by various measurements, e.g., scanning near-field optical microscopy (SNOM) \[15\], scanning single-electron transistor (SET) microscopy \[16\], transport \[17\], and surface-acoustic wave (SAW) \[18\] experiments.

According to the percolation model, the conductivity of the 2DES follows the scaling function \( \sigma \sim (n/n_p - 1)^{\alpha} \), and the exponent \( \alpha \) in a classical percolation transition is 4/3 \[14\]. In Fig. 3, we show the measured \( \sigma \) at \( T = 0.3K \) as a function of \( n/n_p - 1 \) in a log-log scale. Since \( n_p \) is not known beforehand from finite temperature measurements, three trial densities of \( n_p \) are used, in unit of 10\(^{11}\) cm\(^{-2}\), \( n_1 = 0.23 \) (extrapolation to \( \sigma_0 = 0 \) from the low-n regime), \( n_2 = 0.28 \) (extrapolation to \( \sigma_0 = 0 \) from the high-n regime), and \( n_3 = 0.32 \) (critical density of the observed 2D MIT). For \( n_p = n_2 = 0.28 \times 10^{11} \) cm\(^{-2}\), except for some deviation at very low densities, a good linear fit with \( \alpha = 1.31 \), close to 4/3 in the classical model, can be obtained over two decades in \( \sigma \). It is not known, at this stage, whether this coincidence is accidental or the two densities are actually deeply related. On the other hand, for \( n_p = n_1 \) or \( n_3 \), the fittings to a power law behavior are poor. We nevertheless emphasize two important points when applying the percolation model to our data. First, the power law of conductivity in the percolation model only holds for densities very close to \( n_p \), or \( n/n_p - 1 \ll 1 \) \[13\]. Second, percolation transition is essentially a zero-temperature phase transition. As shown in Fig. 1(b), \( \sigma(T) \) does not saturate at our lowest measured \( T = 0.3K \). In this regard, it is necessary that further measurements be carried out at lower temperatures.

In summary, in a high quality Si quantum well specimen, near the apparent 2D metal-to-insulator transition, a linear temperature dependence of conductivity is observed at \( T \) around \( T_F \) on both sides of \( n_c \). When \( \sigma_0 \), the extrapolation of this linear \( \sigma(T) \) to \( T = 0 \), is plotted as a function of density, two regimes with different \( \sigma_0 \) vs \( n \) relations are readily seen. Interestingly, the two linear \( \sigma_0(n) \) regions cross almost exactly at \( n_c \), and \( \sigma_0 \) at the crossing point is \( e^2/h \), the quantum conductance, per square. We also show that the measured \( \sigma(T) \) at our low-T limit can be fitted by a percolation scaling function \( \sigma \sim (n/n_p - 1)^{\alpha} \) when \( n_p = n_2 \), the extrapolation of \( \sigma_0(n) \) to \( T = 0 \) on the high-density side.
