ABSTRACT

Objectives: The purpose of the present review was to evaluate the effect of different bone substitutes used for alveolar ridge preservation on the post extraction dimensional changes.

Material and Methods: An electronic literature search in MEDLINE (PubMed), EMBASE (OVID) and Cochrane (CENTRAL) were performed, in addition to a manual search through all periodontics and implantology-related journals, up to December 2018. Inverse variance weighted means were calculated for all the treatment arms of the included trials for the quantitative analysis.

Results: Forty randomized controlled trials were included in the quantitative analysis. Dimensional changes were obtained from clinical measurements and three-dimensional imaging. The average amount of horizontal ridge resorption was 1.52 (SD 1.29) mm (allograft), 1.47 (SD 0.92) mm (xenograft), 2.31 (SD 1.19) mm (alloplast) and 3.1 (SD 1.07) mm for unassisted healing. Similarly, for all the evaluated parameters, the spontaneous healing of the socket led to higher bone loss rate than the use of a bone grafting material.

Conclusions: The utilization of a bone grafting material for alveolar ridge preservation reduces the resorption process occurring after tooth extraction. However, minimal differences in resorption rate were observed between allogeneic, xenogeneic and alloplastic grafting materials.

Keywords: alveolar bone atrophy; alveolar bone grafting; alveolar process atrophy; bone remodeling; evidence-based dentistry.

Accepted for publication: 5 September 2019

INTRODUCTION

Adequate height and width of the alveolar hard and soft tissues is paramount importance for the placement of dental implants in a functionally and aesthetically optimal position [1]. However, following tooth extraction, the alveolar ridge undergoes physiological remodelling that results in vertical and horizontal osseous reduction, a increase in soft tissue thickness, and a narrowed band of keratinized mucosa [2,3]. These dimensional changes occur predominantly in the horizontal plane and are more pronounced during the first 3 months, followed by gradual reduction thereafter [4]. Previously published systematic reviews have demonstrated that a substantial loss of alveolar ridge volume following tooth extraction may compromise a future implant-supported fixed dental prosthesis [5,6]. Therefore, maintaining the post extraction dimensions will minimize the necessity for alveolar ridge augmentation prior to implant placement.

Alveolar ridge preservation (ARP) is a surgical technique that aims to minimize the degree of post extraction dimensional changes [7]. Various biomaterials, biologic agents, and technical approaches have been proposed. However, contradictory results, regarding the technique and/or material of choice, have been reported. While a recent investigation considered the combination of a xenogenic or allogenic bone substitutes and resorbable collagen sponge or membrane as the most beneficial protocol, other investigations failed to identify a distinctly superior bone substitute when volumetric changes were in question [8,9]. On the other hand, most of the evidence supports the beneficial effect of ARP versus tooth extraction alone [10], concurring with many other previously published systematic reviews and meta-analyses [8,11-16]. A reduction in the soft tissues accompanied by a narrowed band of keratinized mucosa may interfere with future peri-implant diseases [17]. Post extraction keratinized tissue dimensions subsequent to varying ARP techniques and biomaterials do not differ significantly from their changes following spontaneous extraction socket healing [9]. However, a randomized controlled trial revealed better preservation of the facial keratinized mucosa after ARP using combination of corticocancellous porcine bone with a collagen barrier membrane [18]. Consequently, the scientific literature remains inconclusive with regard to the ideal surgical technique and biomaterial necessary to minimize post extraction dimensional changes of the alveolar ridge. Therefore, the aim of the present systematic review was to investigate the impact of different bone substitutes used for alveolar ridge preservation on the post extraction dimensional changes.

MATERIAL AND METHODS

Protocol and registration

The methods of the analysis and inclusion criteria were specified in advance and documented in a protocol. The review was registered in PROSPERO. The present systematic review was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines [10] and the Cochrane Handbook. Additionally, the Assessment of Multiple Systematic Reviews (AMSTAR) checklist was referenced to achieve the predetermined standards of reporting set for conducting systematic reviews [20].

Focus question

The following focus question was developed according to the population, intervention, comparison, and outcome (PICOS) design (Table 1): What is the effect of different bone substitutes in ARP procedures performed in adult human subjects, when compared to unassisted and spontaneous healing of an extraction socket alone, on the prevention of alveolar ridge resorption performed in adult human subjects and reported in randomized controlled trials (RCTs)?

Information sources

An initial electronic systematic search was performed, without any publication date, language or journal restrictions, in the following electronic databases: National Library of Medicine (MEDLINE [PubMed] and ClinicalTrials.gov), EMBASE (OVID) and the Cochrane Central Register of Controlled Trials (CENTRAL).

Search

The following search strategy was designed for the MEDLINE (PubMed) database and then modified accordingly for other database engines: (socket[All Fields] AND (“preservation, biological”)[MeSH Terms] OR (“preservation”[All Fields] AND “biological”)[All Fields]) OR “biological preservation”[All Fields] OR “preservation”[All Fields]) OR (ridge[All Fields] AND (“preservation, biological”)[MeSH Terms] OR (“preservation”[All Fields] AND “biological”)[All Fields]), or (ridge[All Fields] AND (“preservation”[All Fields] AND “biological”)[MeSH Terms]) OR (“preservation, biological”)[MeSH Terms] OR (“preservation”[All Fields] AND “biological”)[All Fields]), or (ridge[All Fields] AND (“preservation”[All Fields] AND “biological”)[MeSH Terms]) OR (“preservation”[All Fields] AND “biological”)[All Fields])
Fields] AND “biological”[All Fields]) OR “biological preservation”[All Fields] OR “preservation”[All Fields]) AND Clinical Trial[ptyp]. The last search was performed on October of 2018. Additionally, to complement the electronic search process, an additional manual search, through the following relevant journals from January 2000 to December 2018, was performed to ensure a thorough screening assessment: “Journal of Periodontology”, “Journal of Clinical Periodontology”, “Clinical Oral Implants Research”, “Clinical Implant Dentistry and Related Research”, “Journal of Dental Research”, “International Journal of Oral and Maxillofacial Implants”, “International Journal of Oral and Maxillofacial Surgery”, and the “International Journal of Periodontics and Restorative Dentistry”. The bibliographies of the retrieved studies and previous published reviews on the topic were also searched for potential articles.

### Selection of studies

After the primary systematic search, all the titles and abstracts were scanned independently by two investigators (JM and AR), followed by the full-text assessment of the potentially eligible studies. In case of any doubt or disagreement between the two authors regarding study selection, a third investigator (FS) was contacted.

### Types of publications

Only human randomized clinical trials have been included. Non-randomized clinical trial studies such as prospective controlled clinical studies, case series, case reports, and retrospective studies were excluded, furthermore, letters, editorials, PhD theses were not considered.

### Types of studies

The included group must have involved utilization of a single bone graft material (no combination of different bone substitutes materials), or spontaneous healing sockets.

### Types of participants/population

Subjects, in which changes in the outcome measures (alveolar ridge dimensions) were assessed either clinically or with the use of three-dimensional radiography with standardization.

### Inclusion and exclusion criteria

A systematic literature search limited to RCTs, without any language restriction, was performed based on the following criteria: studies having recruited a minimum of 5 healthy adult individuals (≥ 18 years old) per study arm who had undergone at least one tooth extraction, while allowing for at least 2 months of healing. The inclusion of a control group (spontaneous socket healing) was not considered necessary to be selected for inclusion. Hence, comparative studies may or may not have included a control group (unassisted socket healing). The approach for the intervention must have involved the utilization of a bone substitute (whether or not it was covered with a barrier membrane) without any additional therapy that may have interfered with the healing outcomes (e.g. growth factors, platelet-rich plasma, immediate implants etc.). The changes in the alveolar ridge dimensions must have been measured either clinically or with the use of three-dimensional radiography that is standardized between visits. Thus, studies that have not assessed clinical outcomes, or those that performed...
two-dimensional radiographic assessment of the ridge dimensions were excluded. All non-randomized studies (i.e. prospective controlled and non-controlled, case series, case reports and retrospective study designs) were also not included. The corresponding authors of potentially eligible studies were contacted, to clarify any uncertainties, ahead of making a final decision. In the absence of a response and/or if the data was insufficient, the study was excluded from the final review.

Data extraction

The data were separately extracted by two investigators (AR and TM) according to the aforementioned criteria to confirm the suitability of each trial. In case of any discrepancies during the data extraction, a third investigator (FS) was referred to for resolution of the matter. The collected data consisted of the following:

- General study characteristics (date and country of publication, participants’ characteristics, number of groups/interventions, and study setting).
- Clinical procedures (bone substitute, membrane type, type of surgical procedure and type of extraction (i.e. flapped versus flapless), and follow-up/healing time).
- Quantitative dimensional changes of the extraction socket.
- Source of funding (e.g. institutional, commercial, self-funded).

Data items

Data were collected and arranged from selected articles in the following fields:

- “Year” - describes the date of publication.
- “Study design” - indicates if the patients were divided in a parallel or split-mouth design.
- “Ridge preservation” - describes a procedure to reduce alveolar bone loss after tooth extraction.
- “Material used in alveolar ridge preservation” - indicates the type of bone graft substitutes (if present) used to restore the damaged extraction socket after tooth extraction.
- “Clinical and radiographic parameters” - revealed the changes in alveolar dimensions during the socket healing process.

Risk of bias within studies

For assessing the quality of the included trials, the same authors (JM and AR), individually examined and categorized the studies according to The Cochrane Risk of Bias Tool for Randomized Controlled Trials [21]. The risk of bias was considered low if a study provided information on all the parameters. A study that had not provided information on even one of the parameters was considered as having a moderate risk of bias, and if a trial or article lacked information about 2 or more parameters, it was categorized as having a high risk of bias.

Statistical analysis

Inverse variance weighted means were calculated for all the treatment arms of the included trials for the quantitative analysis to display the amount (in mm) of ridge resorption in all available and measured dimensions. Ridge resorption of the control groups (unassisted socket healing) was also calculated similarly. Data were expressed as means with standard deviations and all statistical analyses were performed using Rstudio for Macintosh (Rstudio Version 1.1.383, Rstudio, Inc., Massachusetts, USA) and the metafor package.

RESULTS

Study selection

The initial search yielded a total of 1246 studies, from which 549 were excluded subsequent to duplicate removal. Seventeen additional records were identified through direct hand-search of the references and journals. After screening 714 titles and abstracts, 85 studies remained for full-text examination. After thorough evaluation of the studies according to the eligibility criteria, 40 RCTs were included in the quantitative analysis [22-61]. The most frequent reasons for exclusion of the articles were due to:

- the use of biologics, growth factors or healing enhancers, volumetric analyses;
- a histological study design short of clinical data on ridge dimensions;
- immediate implant placement or alternative protocols not within the scope of this review.

Figure 1 displays the screening process leading to the selection of the included 40 trials and data S1 tabulates the causes for extraction of the articles.

Study characteristics

All articles selected for the quantitative analysis reported results of RCTs aimed at evaluating the effect of different bone substitutes on decreasing post extraction alveolar ridge atrophy. All studies except Azizi and Moghaddam [23], that is in Farsi,
were published in the English language. Seven studies were performed in a split-mouth manner [36,52-57], while the rest employed a parallel arm design [22-51,58-61]. Four of the total studies included [58-61] more than 2 treatment arms, while the remaining trials consisted of one comparative treatment group [22-57]. The follow-up time of the included studies ranged from 3 to 8 months. Excluding two multi-center studies [39,60], in Italy and Spain, all the trials were conducted at a single center. The year of publication ranged from 2003 to 2018.

The selection of the 40 trials rendered the inclusion of 1178 subjects (age range from 18 to 81 years old) with a total of 1366 extraction sockets for analysis. Thirty studies performed ARP exclusively on non-molar extraction sockets [22-24,26,27,29-31,33,35,37-41,44-57,61], while the rest included molar sockets as well [25,28,32,36,42,43,58-60]. Information regarding the type of teeth was not available in one article [34]. Except for 11 studies which had utilized three-dimensional radiography for measurement acquisition [27,35-37,39-43,56,57], the outcome measures were taken clinically using a custom-made template for the all other studies [22-26,28-34,38,44-55,58-61]. Two studies [28,39] were performed at a private practice setting only, 2 [23,60] were carried out at both institutional and private practice settings.

![Flowchart of literature search and selection process](http://www.ejomr.org/JOMR/archives/2019/3/e6/v10n3e6ht.htm)
and the remainder were conducted at an institutional setting only \[22-24,27,29-38,40-59,61]\]. Detailed characteristics of the included RCTs are presented in Table 2.

**Allograft**

Sixteen articles, consisting of a total of 394 treated extraction sockets \[26,27,30-33,41,44-46,49-52,56,61\] had reported the use of an allogeneic bone substitute in their study for ARP. The average amount of horizontal ridge resorption was 1.52 (SD 1.29) mm, whereas the loss of ridge height amounted to 0.68 (SD 0.66) and 0.65 (SD 1.29 mm at the mid buccal and mid lingual sites, respectively. In addition, based on two studies that evaluated the horizontal resorption at several reference points below the crest \[45,56\], grafted sockets lost an average of 2.75 (SD 2.05), 1.93 (SD 1.62) and 0.75 (SD 0.79) mm at reference points 1, 3 and 5 mm below the crest. Finally, based on the 2 studies that evaluated the changes in ridge height adjacent to the extraction socket \[33,45\], augmented sockets lost 0.3 (SD 0.55) and 0.45 (SD 0.5) mm at the mesial and distal aspects, respectively.

**Xenograft**

Twenty-two studies, consisting of 455 treated extraction sockets, utilized a xenogeneic bone substitute \[23-25,28,29,34,40,42,43,46,48,51,54,55,58-60\]. On average, the amount of reported resorption in the horizontal dimension was 1.47 (SD 0.92) mm, whereas the loss of ridge height amounted to 0.68 (SD 1.04) and 0.47 (SD 0.97) mm at the mid buccal and mid lingual sites, respectively. Based on the studies that evaluated the horizontal ridge resorption below the crest \[34,36,37,39,40,43\], grafted sockets lost 0.91 (SD 1.46), 0.66 (SD 0.72) and 0.41 (SD 0.58) mm at reference points 1, 3 and 5 mm below the crest, respectively.

**Alloplast**

Seven studies, including 103 sockets reported the use of an osseous alloplast \[22,35,38,47,53,55,58\]. The resorption in the horizontal dimension based on the aforementioned studies was 2.31 (SD 1.19) mm. For the resorption in the vertical plane, only three articles \[35,38,53\] reported this measurement and reporting a loss of 1.23 (SD 1.84) mm at the mid buccal site and 1.07 (SD 0.91) mm at the mid lingual site. Only 1 of the 6 studies \[35\] assessed the changes in the horizontal dimension at reference points below the crest (3.1 [SD 1.6] and 5.7 [SD 3] mm at 3, and 6 mm below the ridge, respectively). The reported vertical bone resorption on the mesial and distal aspects were also measured by one of the studies \[22\], reporting 0.2 (SD 0.6) and 0.4 (SD 0.9) mm, respectively.

**Unassisted socket healing**

Fifteen studies included a total of 161 post extraction sockets that were left to heal without any intervention or addition of a bone substitute \[22-24,27,28,33,36,42,54-57,60\]. The subsequent resorption was 3.1 (SD 1.07) mm in the horizontal dimension, 1.79 (SD 0.98) mm in the mid buccal vertical dimension and 1.53 (SD 1.02) mm in the mid lingual vertical dimension. Based on studies that further evaluated other parameters of socket healing \[34-36,57\], there was 2.98 (SD 2.01) mm of horizontal ridge resorption 1 mm below the crest, 1.59 (SD 1.23) mm at 3 mm below the crest and 0.96 (SD 0.69) mm at 5 mm below the crest. Regarding the ridge height on the mesial and distal areas, an average resorption of 0.52 (SD 0.85) and 0.57 (SD 0.93) mm was reported, respectively \[22,23,25,33,34,52-54\].

**Quality assessment**

The adopted risk of bias assessment for the included RCTs, for criteria and method of reporting, was according to the recommendations of The Cochrane Risk of Bias Tool for Randomized Controlled Trials \[21\] (Table 3). Accordingly, 4 articles were considered to be at a low risk of bias \[37-39,41\], 16 at a moderate risk of bias \[24-27,34-36,40,44,49-52,55,56,61\], and 20 at a high risk of bias \[22,23,28-36,40,44,49-51,53,54,59,60\].

**DISCUSSION**

The clinical benefits of ARP have been extensively demonstrated and robustly evidenced \[7\]. To date, a plethora of scientiffic evidence, consisting of many clinical trials and meta-analyses, have repeatedly shown an attenuated magnitude of ridge resorption with ARP through a diverse set of protocols and techniques \[8,9,12,62\]. The results from this present analysis corroborate previous studies when demonstrating an average horizontal resorption rate of 3.4 (SD 1.07) mm for unassisted socket healing, compared to an average 1.43 (SD 0.89) mm, 1.52 (SD 1.29) mm and 1.84 (SD 1.08) mm.

with the use of xenogeneic, allogeneic, and alloplastic grafting materials, respectively. Additionally, the results in this review also confirm, although based on a limited sample of studies, that proximal sites of the socket exhibited less vertical dimensional reduction, compared to the mid-buccal and mid-lingual sites. And similarly, the horizontal resorption seems to be compared to the mid-buccal and mid-lingual sites.

The magnitude and dynamics of the alveolar ridge’s dimensional changes subsequent to tooth extraction are dictated and influenced by a variety of systemic and local factors, namely the extent of the traumatic injury during extraction, socket morphology, the presence of periodontal disease, the number and thickness of hard and soft tissue phenotype, patient compliance, and most importantly, the number and thickness of the remaining intact socket walls. While this review failed to analyse the effect of such variables due to

### Table 3. Risk of bias assessment for the included randomized controlled trials (according The Cochrane Risk of Bias Tool for Randomized Controlled Trials) [21]

| Study                  | Random sequence generation | Allocation concealment | Blinding of participants and personnel | Blinding of outcome assessment | Incomplete outcome data addresses | Selective reporting | Other bias | Overall risk of bias |
|------------------------|-----------------------------|------------------------|----------------------------------------|-------------------------------|---------------------------------|---------------------|------------|----------------------|

insufficient data and/or significant heterogeneity amongst the included studies, previous systematic reviews and meta-analyses have demonstrated a superior outcome in ridge preservation associated with baseline buccal bone thickness greater than 1 mm [8]. In contrast, a recent RCT concluded that ARP only influences the degree of ridge resorption at sites with ≤ 1 mm of buccal wall thickness [63].

The present investigation was able to analyse a large number of studies grouping the results based on the source of the bone substitutes used. While this method of managing the available data and the analysis of a large heterogenic sample present with inherent limitations, the results revealed similar trends across the included studies. As such, two main conclusions can be drawn: (1) as previously reported, ARP possesses the ability to diminish the resorption process following tooth extraction and (2) there are apparently only minimal differences between the bone substitutes. These results are in concordance with previous investigations reporting similar clinical outcomes associated with ARP using different bone substitutes [30, 55, 61]. Despite this, there is a systematic review and meta-analysis that has reported superior outcomes ascribed to xenogeneic or allogeneic bone substitutes in combination with a collagen sponge or membrane [8]. Despite minimal differences between the bone substitutes, the results of this review also favour both xenogeneic and allogeneic grafting with slightly less resultant resorption.

A primary limitation of the present investigation is the inclusion of multiple different grafting techniques and barrier membranes in the analysis. Another limitation includes several local and systemic factors known to play a role in the remodelling process that could not be evaluated. Also, the variation between the time points for evaluating the resorption process may have played a significant role in the reported outcomes. The weighted mean values of the different materials should be read and considered with caution as no statistical comparisons have been performed between the different treatment groups of bone grafts.

Finally, it is important to bear in mind that while ARP is most often performed in preparation for posterior implant placement, implant-related outcomes are often underreported in these investigations. As such, future studies should evaluate outcomes such as the feasibility of implant placement, the need for further grafting, as well as the long-term implant survival and success rates when placed into sockets previously grafted with different materials. Similarly, patient-reported outcomes have rarely been investigated with regards to ARP.

**CONCLUSIONS**

Alveolar ridge preservation with the use of different bone substitutes represents an effective method for diminishing the physiological resorption process after tooth extraction. Additionally, minimal differences in resorption rate were observed between allogeneic, xenogeneic and alloplastic grafting materials.

**ACKNOWLEDGMENTS AND DISCLOSURE STATEMENTS**

The authors thank Dr. Shayan Barootchi (Department of Periodontics and Oral Medicine, University of Michigan School of Dentistry, Ann Arbor, Michigan, USA) for his assistance in conducting the statistical analysis.
