We have observed thermalization by elastic collisions of magnetically trapped metastable helium atoms. Our method directly samples the reconstruction of a thermal energy distribution after the application of an RF knife. The relaxation time of our sample towards equilibrium gives an elastic collision rate constant of $\alpha \sim 5 \times 10^{-9}$ cm$^3$/s at a temperature of 1 mK. This value is close to the unitarity limit.

Bose-Einstein condensation (BEC) of dilute atomic vapors has been observed in Rb, Na, Li, and H. Atoms in these gases are in their electronic ground state. Metastable helium in the $^2S_1$ state (He*), which has long been of interest to the laser cooling community, is by contrast in a state 20 eV above the ground state. This situation presents new possibilities for the study of cold dilute atomic gases. First, the large internal energy permits efficient detection by ionization of other atoms and surfaces: it is possible to study very small samples. Second, Penning ionization by both the background gas and between trapped atoms offers a high time resolution monitor of the number and density of trapped atoms. Third, the possibility of using the large internal energy of He* for atomic lithography has already been demonstrated, and this application as well as atom holography may benefit from highly coherent sources. Finally, much theoretical work has already been devoted to estimation of the elastic collision cross sections on the one hand and Penning ionizing rates on the other. Experiments such as the one reported here can test this work.

BEC is achieved in dilute gases by evaporative cooling of a magnetically trapped sample. In He*, it is hampered by the fact that in a magneto-optical trap, the typical starting point of magnetic trapping, the achievable atomic density is limited by a large light-assisted Penning ionization rate. On the other hand, the scattering length for low energy elastic collisions is predicted to be quite large, and the Penning ionization rate highly suppressed in a spin polarized sample. He* in a magnetic trap necessarily constitutes a spin polarized sample and experiments have already demonstrated a suppression of more than one order of magnitude. If the theoretical estimates are right, efficient evaporative cooling may still be possible in spite of the low initial trap density. We report here the observation of the thermalization of He* due to elastic collisions which appears to roughly bear out the predictions.

To perform a thermalization experiment, a trapped cloud is deliberately placed out of equilibrium and its relaxation due to elastic collisions between trapped particles is observed. Usually the observations are made by imaging the spatial distribution as a function of time. In our experiment the relaxation is observed in the energy distribution of the atoms in the magnetic trap. First this distribution is truncated above $E_{RF}$ by a radio-frequency pulse (or RF knife) of frequency $\nu$. The cloud rethermalizes by elastic collisions and the population of the states of energy higher than $E_{RF}$ increases from zero; for large times compared to the thermalization time $\tau_{th}$ the distribution reaches a thermal distribution. With the help of an analytical model and numerical simulations, we deduce $\tau_{th}$ from the time dependence of the number of atoms with energy above $E_{RF}$. We measure this time dependence by applying a second RF knife after a delay time $t$, and with a frequency slightly above that of the first one. Our model also allows us to relate $\tau_{th}$ to the elastic collision rate per atom in the trap.

Much of our setup has been described previously. Briefly, we use a LN$_2$ cooled DC discharge source to produce a beam of metastable He atoms. The beam is slowed down to $\sim 100$ m/s using Zeeman slowing and loads a magneto-optical trap. Typically, $3 \times 10^8$ atoms are trapped at a peak density of $3 \times 10^9$ at/cm$^3$, limited by light-induced Penning ionization. The temperature of the cloud is about 1 mK and the cloud is roughly spherical with an RMS size of 2.5 mm. We then apply a 5 ms Doppler molasses to cool the atoms down to 300 $\mu$K. This is achieved by switching off the magnetic field, decreasing the detuning close to resonance and lowering the intensity to 10% of its value in the MOT. An optical pumping step allows us to trap up to $1.5 \times 10^8$ atoms in a Ioffe-Pritchard trap. We use a "cloverleaf" configuration with $B' = 85$ G/cm, $B'' = 25$ G/cm$^2$ and a bias field $B_0 = 200$ G. The two sets of coils are outside the vacuum, separated by 4 cm. After lowering the bias field to 4 G, the temperature of the compressed atomic sample reaches 1 mK. The lifetime of the trap is 60 s.

We use a 2 stage microchannel plate (MCP) to detect the atoms. The MCP is placed 5 cm below the trapping region and has an active area of 1.4 cm diameter. Two grids above the MCP allow us to repel all charged particles and detect only the He*. After turning off the magnetic trap, the MCP signal corresponds to a time of flight spectrum (TOF) which gives the temperature of the atoms. The area of this spectrum is proportional to the number of atoms in the trap at the time it was turned
The collection and detection efficiency of the MCP varies by roughly a factor of two depending on the magnetic field configuration we use, and so one must take care to only use data corresponding to the same magnetic field when making comparisons. We also use the MCP to monitor the atoms falling out of the trap while applying an RF knife. The area of the MCP signal in this case measures the number of atoms with an energy above that of the RF knife. Finally, when we bias the grids so as to attract positive ions, the MCP signal can be used to observe the products of Penning ionization with the background gas while the trap is on. This signal is proportional to the number of trapped atoms. We observe an exponential decay, indicating that two body loss (He* + He*) is negligible.

Two parallel coils in the vacuum system produce an RF magnetic field perpendicular to the bias field and constitutes the RF knife. To understand the effect of the RF knife on the trapped cloud and to assure that our sample is at thermal equilibrium, we first performed an RF spectroscopy measurement of the energy of the atoms in the trap [24]. We apply an RF pulse at a frequency \( \nu \) which changes the Zeeman sublevel of the atoms from the \(+1\) state to \( +1 \) state. The duration of the knife is 3 s, which is necessary to expel all the atoms with energy above \( h\nu \) over the entire range which we explore. We then turn off the magnetic trap to measure the number of remaining atoms. Observation of the atoms falling onto the MCP during the RF knife shows that the flux of atoms expelled is negligible at the end of the pulse. An example of the RF spectrum is shown in Fig. 2a. The derivative of the data gives the energy distribution. In Fig. 2b) we compare this distribution with a thermal one at 1.1 mK, the temperature measured by an independent TOF measurement. We conclude that our atomic sample is close to thermal equilibrium.

We begin the thermalization experiment with a 2 s RF knife of frequency \( \nu_1 = 135 \) MHz (corresponding to \( \eta = (h\nu - 2\mu_B B_0)/k_B T \sim 6 \)). Next we measure the number of atoms falling onto the MCP during a second RF knife at a slightly higher frequency (\( \nu_2 = 138 \) MHz) and delayed by a time \( t \). Assuming that the angular distribution of the atoms expelled by the second RF knife is constant during the thermalization process, the MCP signal is proportional to the number of expelled atoms. Plots of the number of expelled atoms as a function of \( t \) are shown in Fig. 2 for samples having different numbers of atoms but the same temperature to within 10%. Fig. 2 shows that the number of atoms above the RF knife increases rapidly and then falls again with a time constant close to the trap lifetime as atoms are lost. If the initial increase is indeed due to thermalizing collisions, the initial slope of each curve should be proportional to the square of the number of atoms. Our data roughly confirm this dependence.

To be more quantitative, and to determine the thermalization time \( \tau_{th} \), we use a model based on the Boltzmann equation under the sufficient ergodicity hypothesis and inspired by [25]. We divide the sample into two energy regions, \( E_- \) and \( E_+ \), with energies below and above \( \eta k_B T \) respectively and denote by \( N_- \) and \( N_+ \) the number of atoms belonging to the two regions. We assume that \( \eta \gg 1 \). Immediately after truncation, \( N_+ = 0 \), and we seek a differential equation governing the time dependence of \( N_+ \). Since \( \eta \approx 1 \), we only take into account collisions of the type \( (E_-) + (E_-) \leftrightarrow (E_-) + (E_+) \), and neglect all collisions involving two atoms in \( E_+ \) in either the final or initial state. The corresponding flux \( \dot{N}_+ \) is thus of the form

\[
\dot{N}_+ = \Delta_1 N_-^2 - \Delta_2 N_- N_+.
\]  

The coefficients \( \Delta_1 \) and \( \Delta_2 \) are calculated using Boltzmann equation [25]. In particular \( \Delta_1 N_- \) is exactly the evaporation rate in an evaporative cooling process [25].
If we make the further approximations that the atoms in $E_-$ and $E_+$ have thermal distributions \cite{26}, neglect variations of the temperature during thermalization and assume that the collision cross section $\sigma$ is independent of velocity, $\Delta_1$ and $\Delta_2$ are analytic functions of the trap parameters, atomic mass $m$, $\gamma$ and $\mu_B B_0/k_B T$. This latter parameter appears because our trap cannot be approximated by an harmonic trap; we use the semilinear form \cite{25}. It is straightforward to take into account the finite lifetime $\tau$ of the atomic sample since $N_-(t) + N_+(t) = N_-(0) \exp(-t/\tau)$. The solution of the resulting differential equation is:

$$N_+(t) = N_{th} e^{-t/\tau} \left[1 + \frac{q}{1 - q - \exp\left(\frac{q}{\tau_{th}}(1 - e^{-t/\tau})\right)}\right]$$

where $\tau_{th}^{-1} = \frac{\gamma_{el} \sigma}{\sqrt{2} q \sqrt{1 - q} \sqrt{\gamma_{el} \sigma}}$ and $N_{th} = (1 - q) N_-(0)$.

The elastic collision rate is $\gamma_{el} = n \sigma \bar{\nu}$ with $n$ defined at the center of the trap and $\bar{\nu} = 4 \sqrt{k_B T/\pi m}$. The quantities $V_{ev}$, $V_\sigma$ and $q$ are defined as in \cite{25,27}; they are analytic functions of $\eta$ and $\mu_B B_0/k_B T$. The quantity $q$ is the ratio of the number of atoms below the RF knife to the total for a thermal distribution (about 0.9 under our conditions), and $N_{th}$ is the asymptotic value of $N_+$ for infinite trap lifetime. Numerical simulations of the energy form of Boltzmann equation are in good agreement with our model for $\eta > 10$; for $\eta = 6$ the quantity $\gamma_{el} \tau_{th}$ is 1.8 times larger meaning that our assumption about the distribution function fails for small $\eta$ \cite{27}. We take this factor into account in calculating $\gamma_{el}$.

To fit the data of Fig. 2 with eq. (2), we fix the lifetime $\tau$ at its measured value and use $\tau_{th}$ and $N_{th}$ as adjustable parameters. The uncertainty in $\tau_{th}$ is estimated by varying the lifetime of the trap within its uncertainty range and looking at the resulting dispersion in $\tau_{th}$. The uncertainty in the number of trapped atoms is estimated from the dispersion of the TOF area measurements before and after taking a curve as in Fig. 3. The exact value of $q$ has little influence on the fit.

We have made several tests to check the consistency of our results. First, we have checked that the fitted value of $N_{th}$ corresponds to the expected fraction of atoms above the knife for our temperature. Second, Fig. 3 shows that $\tau_{th}^{-1}$ is proportional to the number of trapped atoms, as it must be if the process of refilling of the upper energy class is due to two body collisions. We can exclude any effect independent of the number of atoms. The line passing through the origin uses the slope as a fit parameter and has $\chi^2 = 5$ for 8 degrees of freedom. Third we have done an additional experiment that confirms the presence of elastic collisions: in a trap decay rate experiment, in the presence of the RF knife, the ion signal exhibits a clear non-exponential behaviour at short times. This effect can be satisfactorily interpreted as elastic collisions bringing atoms above the RF knife and hence allows a measurement of the evaporation rate. This rate is consistent with the results obtained in our thermalization experiment. Fourth we have checked that heating cannot explain the repopulation of the upper energy classes. With the trap undisturbed, we can place an upper limit on the heating rate of 25 $\mu$K in 60 s. This limit is two orders of magnitude too low to explain our data. Lastly, we have performed the thermalization experiment for different lifetimes of the magnetic trap (20, 40 and 60 s) and found consistent results.

From our data in Fig. 3, we can deduce an accurate measurement of the thermalization time; the fit gives $\tau_{th} = 3.0 \pm 0.3$ s for the densest sample. Using the measured temperature and bias field, this value of $\tau_{th}$ leads to $\gamma_{el} = 6 \pm 1$ s$^{-1}$; this result depends on the accuracy of our thermalization model. To find the rate constant $\alpha = \gamma_{el}/n$, we must estimate the density. Since the data

\[\]
show that our sample is close to thermal equilibrium, we can calculate the volume of the trap knowing the trap parameters. The absolute measurement of the number of atoms is performed by measuring the total power absorbed from a saturating laser beam, similar to [15]. A TOF area of 75 mV.s corresponds to $10^8$ atoms in the magnetic trap with an uncertainty of a factor of 2. This leads to $\alpha = 5 \times 10^{-9}$ cm$^3$/s to within a factor 3 at $T = 1 \pm 0.1$ mK. The ENS-Paris group has obtained a similar result with a different measurement [28]. The unitarity limit at that temperature is $\alpha \sim 10^{-8}$ cm$^3$/s. This means that it is probably not valid to use a constant elastic cross section in our model and some deviation might appear in the quantity $\gamma_{el} \tau_{th}$. We are currently investigating refinements to our thermalization model.

The results shown here are very encouraging for evaporative cooling of He* in search of BEC.

We thank P. Leo and P. Julienne and the ENS helium group for helpful discussions. This work was partially supported by the EC under contracts IST-1999-11055 and HPRN-CT-2000-00125, and DGA grant 99.34.050
