**A B S T R A C T**

We report a case of persistent *Candida orthopsilosis* associated septic arthritis. Repeated isolation of *C. orthopsilosis* from tissue and joint fluid was confirmed by identification of the ITS region of the rRNA gene using a *Candida*-Specific Luminex based assay and gene sequencing of the D1/D2 regions. This was the first case of *C. orthopsilosis* associated septic arthritis reported in Jamaica and in the literature.

We present a case of *C. orthopsilosis* infection associated with septic arthritis in a 28-year-old male presented at UHWI with a history of SLE. To the best of our knowledge this was the first case seen at the UHWI with no previously reported cases in Jamaica or in the literature.

1. **Introduction**

The use of phenotypic methods has been limited in identifying closely related *Candida* species. Using genotypic methods, the clonally related species of *Candida orthopsilosis* complex was subsequently divided into groups 1, 2 and 3 identified under the corresponding names; *Candida parapsilosis*, *C. orthopsilosis* and *Candida metapsilosis* [1]. These were of sufficient differences to make them distinctly different species and should be viewed as separate clinical and epidemiological entities. These species have been implicated in several clinical conditions but with varying frequencies, including sex and age related differences [2].

*C. parapsilosis* is a major cause of disease in the immuno-compromised individual while *C. orthopsilosis* is comparatively rare in human infection despite its isolation from several clinical specimens [2–6].

Riccombeni et al. identified 5700 protein coding genes in *C. orthopsilosis*, the majority of which were similar to those found in *C. parapsilosis* [5]. These findings suggest that virulence of this species may be associated with expansion of gene families.

Up to 1992 only eight *C. parapsilosis* associated cases of septic arthritis were reported in the literature, seven of which followed replacement of a joint prosthesis, joint injection, or arthrocentesis [7]. To date, after an extensive literature search, no cases of septic arthritis caused by *C. orthopsilosis* have been reported.

2. **Case**

In March 2001 a 17-year-old Jamaican male diagnosed with Systemic Lupus Erythematosus (SLE) presented to the University Hospital of the West Indies (UHWI) rheumatology clinic with high fever, severe joint pains, proteinuria, and bilateral ankle edema. At that time, tests for both ANA and anti-DNA antibodies were positive, and a renal biopsy showed class I glomerulonephritis. He was treated with high dose steroids, which were quickly tapered because of steroid induced diabetes. His proteinuria decreased, but without clinical resolution. The patient was therefore kept on Prednisone 20 mg daily with Mycophenolate Mofetil (MMF). The patient was readmitted in January 2002 and was regularly monitored with frequent blood cultures for sepsis, which yielded sterile cultures for microbiological investigations. The patient was however treated with augmentin following positive urine culture of *Escherichia coli*. His third admission in May 2002 was subsequent to a diagnosis of pylonephritis and skin sepsis.

Between January 2001 and May 2004 the patient had several clinic visits including sixth admissions to wards for fever and joint pains, pleurisy and renal flare. Pleural fluid and blood cultures were...
negative. In 2005 he developed bilateral avascular necrosis of the shoulders. He also experienced another renal flare with significant proteinuria (3.7 g per 24 h) but normal serum creatinine. From 2006 until 2009 he had frequent clinic visits and admissions because of fever, increased proteinuria and knee swelling.

Following recurrent painful swelling of the left knee in 2008, several aspirations of joint fluid were collected, yielding inflammatory fluid with negative bacterial cultures. Each aspiration was followed by a corticosteroid injection. Radiographs of the knees showed flattened condyles, presumably due to previous avascular necrosis (Fig. 1). Aspirations and steroid injections did not have any lasting effect as the left knee became increasingly painful several weeks after each aspiration. Despite negative cultures, antibiotics were prescribed but never produced any positive results. In August 2009 the renal status significantly deteriorated, necessitating one gram IV Methylprednisolone for 5 days. How-ever, this treatment did not stabilize the renal inflammation and the patient was started on dialysis after another renal flare with acute renal failure.

Between March 2011 and February 2012, repeated cultures of tissue and joint fluids of the left knee on saboraud dextrose agar and mycobiotic agar, yielded yeast in pure cultures and were assigned to this species. These isolates were confirmed as *C. orthopsilosis* using PCR primers D1: GCA TAT CAA TAA GCG GAG GA and D2: TTG GTC CGT GTT TCA AGA CG for amplification and sequence analysis of the ribosomal large subunit, D1/D2 and the internal spacer region of the rRNA as outlined by Deak et al. [8]. A Candida-specific Luminex-based assay using Probe CO (*C. orthopsilosis*) with a nucleotide sequence (5’ to 3’) of AA AAT TCT TCC AAA TTC GAC was used for rapid identification of the present isolate [8]. Primers used in the Luminex-based assay were ITS 3: GCA TCG ATG AAG AAC GCA GC and ITS4–BIOTIN: TC CTC CGC TTA TGC ATA TGC.

Among the many matches of *C. orthopsilosis* in Genbank we provide two strains including 100% match to Genbank # HM 755978.1 and HM 755977.1 (respectively equal to *C. orthopsilosis* strain ATCC 20504 and *C. orthopsilosis* strain ATTC 20503).

The minimal inhibitory concentration micro-dilution assay described by the National Committee for Clinical Laboratory Standards (NCCLS) [9] was performed on the *C. orthopsilosis* isolate and yielded susceptibilities to amphotericin B (AMB) ≤ 0.03 mg/L; fluconazole 0.25 mg/L; itraconazole ≤ 0.03 mg/L; posaconazole 0.06 mg/L; voriconazole ≤ 0.03 mg/L; fluconazole (5-FC) ≤ 0.125 mg/L; and ketoconazole 0.25 mg/L.

3. Discussion

*C. orthopsilosis* remains a rare entity in fungal associated human infections. Before 2005, *C. orthopsilosis* (group 2 strain) was yet to be differentiated from its closely related group 1, *C. parapsilosis*, and understandably so, as all previously associated infections were assigned to this species. Several studies to adjust the number of infections previously attributed to *C. parapsilosis*, revealed estimated frequencies varying from 1.4% with *C. orthopsilosis* and 1.7% with *C. metapsilosis* in Spain to 10.9% and 23.8% in South America and Malaysia [3–6,10].

To date however, there has been no reported case of *C. orthopsilosis* associated arthritis following an extensive literature search. It is interesting to note that the present case is similar to previous cases where *C. parapsilosis* was implicated in arthritis in which there were persistent infections over several months despite antifungal treatment [11]. Consistent with these findings, is the prolonged period of treatment with fluconazole in the present case, but with no signs of improvement and the continued isolation of the yeast in pure culture. The prognosis therefore remains unclear, as the patient continues on fluconazole without any signs of resolution over the several months since antifungal therapy was first initiated.

Current reports on epidemiological studies have described *C. orthopsilosis* in only a few sporadic cases of clinical relevance [3–6,11]. However, its ability to infect and cause human diseases, appear to be similar to closely related *Candida spp*. *C. parapsilosis* for example, is closely related to *C. orthopsilosis* with many of their protein-coding genes having an ortholog in *C. parapsilosis* [5]. Of noteworthy interest, is a report on virulence by Gacser et al. [12]. They reported *C. orthopsilosis* as producing severe attenuation and morphological changes on reconstituted human tissue models [12].

Majority of the *C. parapsilosis* associated arthritis cases reported in the literature occurred with elderly patients (> 60 years) following instrumentation of joints for placement of a joint prosthesis, joint injection, or arthrocentesis [7,13,14]. Comparatively, our patient is much younger (24 years at diagnosis) with a pre-compromised immune system apparently resulting from autoimmune disease SLE, and the frequent use of cortico-steroids introduced in patient therapy.

The persistence of infection seen in a number of *Candida* affected cases, appear to be more likely, the result of biofilm formation [15]. Biofilm formation confers significant resistance to antifungal therapy by limiting the penetration of antifungal drugs,

**Fig. 1.** Radiograph of the left knee showing flattened condyles, presumably due to previous avascular necrosis. There is a marked periosteal reaction with mixed areas of lucency and sclerosis, suggestive of septic arthritis and osteomyelitis.
as well as, protect cells from host immune responses [15]. Some strains of C. orthopsilosis are able to form biofilms on silicone elastomer discs, which would increase the ability of the yeast to infect and cause disease [16]. Production of biofilms is a primary virulence factor of C. parapsilosis and apparently of greater significance than the small amount produce by C. orthopsilosis and C. metapsilosis [17].

Interestingly, the mortality rate of patients at an Italian University Hospital from whom were isolated C. parapsilosis which form biofilm in vitro, was 71.4% compared to 28% from those with biofilm-deficient isolates [11].

It is important to note that filamentous C. parapsilosis phenotypes generated more biofilm, and were more invasive into agar than strains, which remained predominantly in yeast forms [18]. The present C. orthopsilosis isolate is notably, a pseudohyphal yeast, observed on cornmeal agar.

The virulence of C. orthopsilosis and its capacity to produce disease has not been extensively studied. However, its closely genetically related C. parapsilosis [1] would reasonably suggest a strong possibility of similar invasiveness and clinical relevance of the two species. The prolonged treatment with fluconazole in the present case is similar to other cases of septic arthritis associated with C. parapsilosis [13].

Failure to carry out early investigations for fungal arthritis in our patient was probably due to the apparent lack of clinical suspicion. Presumably, as also seen in C. parapsilosis related cases, the source and dissemination of C. orthopsilosis, may have resulted from multiple injections of steroids in the joint including aspirations of joint fluid. The source of the organism may also have resulted from the contaminated hands of healthcare providers, which have been implicated in the transmission of C. parapsilosis [19]. A hematogenous spread of the yeast may have followed severe renal impairment, hemodialysis and avascular necrosis.

After 12 months of fluconazole therapy, C. orthopsilosis was isolated from joint fluid and tissue in pure cultures of the organism. MICs on repeated isolations of the fungus at different times, did not show any significant changes and remained at a low level of concentration for all the MICs done.

The repeated isolation of C. orthopsilosis in pure cultures followed by prolonged fluconazole therapy was consistent with the persistence of infection seen with other arthritic cases due to C. parapsilosis [19].

It is in our view, that the persistence of infection is a consequence of biofilm formation decreasing the concentration of fluconazole in the synovial fluid [15,17]. We believe that the resolution of this fungal infection will require the full course of continued treatment with fluconazole over a prolonged period of up to two years of antifungal therapy [15,17,20]. However, in the event of non-responsiveness to fluconazole, the echinocandins antifungals may prove useful, as they have shown high activity against biofilm forming Candida species [15,17]. Together with the appropriate management of the patient and the timely monitoring with cultures, may also play an important role in achieving complete clearance of the yeast.

Ethical statement

Written informed consent was obtained from the patient for publication of this Case report and any accompanying images. A copy of the written consent is available for review from the Series Editor of this journal.

Conflict of interest

There are none.

Acknowledgments

We acknowledge Dr. Shawn Lockhart and his staff at the Antifungal and Fungal Reference Laboratories, Mycotic Diseases Branch, Centers for Disease Control and Prevention (CDC) for genotyping the isolate.
