Single-qubit channels are studied under two broad classes: amplitude damping channels and generalized depolarizing channels. A canonical derivation of the Kraus representation of the former, via the Choi isomorphism is presented for the general case of a system’s interaction with a squeezed thermal bath. This isomorphism is also used to characterize the difference in the geometry and rank of these channel classes. Under the isomorphism, the degree of decoherence is quantified according to the mixedness or separability of the Choi matrix. Whereas the latter channels form a 3-simplex, the former channels do not form a convex set as seen from an ab initio perspective. Further, where the rank of generalized depolarizing channels can be any positive integer upto 4, that of amplitude damping ones is either 2 or 4. Various channel performance parameters are used to bring out the different influences of temperature and squeezing in dissipative channels. In particular, a noise range is identified where the distinguishability of states improves inspite of increasing decoherence due to environmental squeezing.

I. INTRODUCTION

Open quantum systems are ubiquitous in the sense that any system can be thought of as being surrounded by its environment (reservoir or bath) which influences its dynamics. They provide a natural route for discussing damping and dephasing. One of the first testing grounds for open system ideas was in quantum optics [1]. Its application to other areas gained momentum from the works of Caldeira and Leggett [2], and Zurek [3], among others.

If the system and environment start out in product state, then the evolution of the state $\rho$ can be described by the quantum process $\rho' = \mathcal{E}(\rho)$. It can be given an operator sum representation or Kraus representation $\mathcal{E}(\rho) = \sum_j E_j \rho E_j^\dagger$, (1)

where $\sum_j E_j^\dagger E_j = \mathcal{I}$. The operators $E_j$ are called Kraus operators or the operator elements of operation $\mathcal{E}$. It may be noted that the converse problem, that of deducing the underlying Lindbladian process that generates a given completely positive (CP) map on the density operator, is computationally hard. Complexity theoretically, it is known to be NP-hard [4].

A result now familiar in quantum information theory is the isomorphism between the trace-preserving, CP maps on a $d$-dimensional system (qudit) and the $d^4 - d^2$ dimensional space of two-qudit density operators $\rho$ which are maximally mixed on one of the particles [5, 9]. One way to obtain the state from the channel is to apply the latter on one half of a maximal two-qudit entangled state. The resulting state is called the Choi matrix. In the converse direction, a unique qudit channel can be associated with such each Choi matrix via the notion of gate teleportation [10]. It can be shown that the Kraus operators for the qudit channel can be derived by diagonalizing the Choi matrix [11, 12], obtained also by constructing the dynamical map for the transformation [13, 14].

In this work, we derive the Kraus operators for the squeezed generalized amplitude damping (SGAD) channel in its canonical form via the Choi matrix method, and establish its unitary equivalence to a previous derivation [15], where the connection to the amplitude damping (AD) and generalized amplitude damping (GAD) channels was manifest. The channel-state isomorphism is used to study and contrast amplitude damping channels and generalised depolarising channels geometrically. Understanding the geometry of 1-qubit channels is important as it can simplify the study of other problems, such as channel capacity [16]. Finally the contrastive roles of temperature and squeezing in the case of the SGAD channel are noted.
II. SOME PHYSICALLY MOTIVATED SINGLE-QUBIT CHANNELS

Depending upon the system-reservoir ($S - R$) interaction, open systems can be broadly classified into two categories, viz., quantum non-demolition (QND) or dissipative. A particular type of (QND) $S - R$ interaction may be achieved when the Hamiltonian $H_S$ of the system commutes with the Hamiltonian $H_{SR}$ describing the system-reservoir interaction, i.e., $H_{SR}$ is a constant of the motion generated by $H_S$ [17–21]. This results in pure dephasing without dissipation. Investigation into pure dephasing scenarios was originally motivated by the problem of the detection of gravitational waves [22–23]. A dissipative open system would be when $H_S$ and $H_{SR}$ do not commute resulting in dephasing along with damping [24]. Impressive progress has been made on the experimental front in the manipulation of quantum states of matter towards quantum information processing and quantum communication. Myatt et al. [24] and Turchette et al. [25] performed a series of experiments in which they engineered both the pure dephasing as well as dissipative type of evolutions. In another experiment [27], a QND scheme of measurement was characterized using only simple linear optics devices. An experimental investigation of the dynamics of different kinds of bipartite correlations, in an all-optical setup was made in [28]. In [29], an interesting experiment was presented, in which dissipation induces entanglement between two atomic objects. Here we briefly discuss the two processes, QND as well as dissipative as applicable to single qubit channels. In this work we model the reservoir by a squeezed thermal bath. An advantage is that the decay rate of quantum coherence can be suppressed leading to preservation of nonclassical effects [17, 30, 31]. A squeezed reservoir may be constructed on the basis of establishment of squeezed light field [32]. Experiments probing the squeezed-light-atom system have been carried out in Refs. [33, 34]. All the results pertaining to the usual thermal bath can be obtained by setting the bath squeezing parameters to zero.

A. QND Channel

Following [17], the evolution equation for a system, e.g., a qubit, interacting with its environment by a coupling of the energy-preserving QND type where the environment is a bosonic bath of harmonic oscillators initially in a squeezed thermal state, initially decoupled from the system, in the system eigenbasis denoted by the subscripts $n, m$, is:

$$\frac{d}{dt} \rho_{nm}^{s}(t) = \left[ -\frac{i}{\hbar} (\epsilon_n - \epsilon_m) + i\eta(t)(\epsilon_n^2 - \epsilon_m^2) - (\epsilon_n - \epsilon_m)^2 \dot{\gamma}(t) \right] \rho_{nm}^{s}(t),$$

where

$$\eta(t) = -\sum_k \frac{g_k^2}{\hbar^2 \omega_k^2} \sin(\omega_k t),$$

and

$$\gamma(t) = \frac{1}{2} \sum_k \frac{g_k^2}{\hbar \omega_k} \coth \left( \frac{\beta \hbar \omega_k}{2} \right) \left| (e^{i \omega_k t} - 1) \cosh(r_k) + (e^{-i \omega_k t} - 1) \sinh(r_k) e^{2 \Phi_k} \right|^2.$$

Here $\omega_k$ is the reservoir oscillator frequency, indexed by subscript $k$, $\beta = 1/k_B T$ and $g_k$ is the system-reservoir coupling term. For the case of zero squeezing, $r = \Phi = 0$, and $\gamma(t)$ given by Eq. (4) reduces to the expression obtained earlier [18–21] for the case of a thermal bath. It can be seen that $\eta(t)$ [3] is independent of the bath initial conditions and hence remains the same as for the thermal bath. Note that in Eq. (2), the term responsible for the decay of coherences, i.e., the coefficient of $\dot{\gamma}(t)$ is dependent on the eigenvalues $\epsilon_n$ of the ‘conserved pointer observable’ operator which in this case is the system Hamiltonian itself. This reiterates the observation that the decay of coherence in a system interacting with its bath via a QND interaction depends on the conserved pointer observable and the bath coupling parameters [19]. The channel corresponding to the evolution generated by Eq. (2) is called the phase flip channel [17–21]. More generally, phase flip channels are a subset of Pauli or generalized depolarising channels, which are unital, i.e., they map the identity matrix to itself.

B. Dissipative Channel

Consider a two-level system (qubit) interacting with a squeezed thermal bath in the weak Born-Markov, rotating wave approximation. The system Hamiltonian is given by $H_S = (\hbar \omega/2) \sigma_z$. The system interacts with the reservoir via the atomic dipole operator which in the interaction picture is given as $\tilde{D}(t) = \tilde{d} \sigma_- e^{-i \omega t} + \tilde{d}^* \sigma_+ e^{i \omega t}$ where $\tilde{d}$ is the
transition matrix elements of the dipole operator. The master equation depicting the evolution of the reduced density matrix operator of the system $S$ in the interaction picture has the following form \[15, 24\]

$$
\frac{d}{dt} \rho_s(t) = \gamma_0(N + 1) \left( \sigma_- \rho_s(t) \sigma_+ - \frac{1}{2} \sigma_+ \sigma_- \rho_s(t) - \frac{1}{2} \rho_s(t) \sigma_+ \sigma_- \right) \\
+ \gamma_0 N \left( \sigma_+ \rho_s(t) \sigma_- - \frac{1}{2} \sigma_- \sigma_+ \rho_s(t) - \frac{1}{2} \rho_s(t) \sigma_- \sigma_+ \right) \\
- \gamma_0 M \sigma_+ \rho_s(t) \sigma_+ - \gamma_0 M^* \sigma_- \rho_s(t) \sigma_-. 
$$

(5)

Here $\gamma_0$ is the spontaneous emission rate given by $\gamma_0 = (4\omega^3|\langle \vec{d} |^2)/(3\hbar c^3)$, and $\sigma_+$, $\sigma_-$ are the standard raising and lowering operators, respectively given by $\sigma_+ = |1\rangle \langle 0| = \frac{1}{2} (\sigma_x + i\sigma_y)$ and $\sigma_- = |0\rangle \langle 1| = \frac{1}{2} (\sigma_x - i\sigma_y)$. Eq. (5) may be expressed in a manifestly Lindblad form as \[35\]

$$
\frac{d}{dt} \rho_s(t) = \sum_{j=1}^{2} \left( 2R_j \rho_s R_j^\dagger - R_j^\dagger R_j \rho_s - \rho_s R_j R_j^\dagger \right),
$$

(6)

where $R_1 = (\gamma_0(N_{th} + 1)/2)^{1/2} R$, $R_2 = (\gamma_0 N_{th}/2)^{1/2} R^\dagger$ and $R = \sigma_- \cosh(r) + e^{i\Phi} \sigma_+ \sinh(r)$. This guarantees that the evolution of the density operator is CP. If $T = 0$, then $R_2$ vanishes, and a single Lindblad operator suffices to describe Eq. (5). Also

$$
N = N_{th}(\cosh^2(r) + \sinh^2(r)) + \sinh^2(r),
$$

(7)

and $M = -\frac{1}{2} \sinh(2r) e^{i\Phi} (2N_{th} + 1)$. Here $N_{th} = 1/(e^{\hbar \omega/k_B T} - 1)$ is the Planck distribution giving the number of thermal photons at the frequency $\omega$; $r$ and $\Phi$ are bath squeezing parameters. The general map generated by the Eq. (5) is the SGAD channel \[15\], which generalizes the notion of the AD and GAD channels \[5\]. These amplitude damping channels are non-unital and contractive, mapping any initial state to a unique asymptotic state.

### III. SOME PROPERTIES OF THE KRAUS REPRESENTATION OF DISSIPATIVE AND NON-DISSIPATIVE CHANNELS

A superoperator $\mathcal{E}$ due to interaction with the environment, acting on the state of the system is given by

$$
\rho \rightarrow \mathcal{E}(\rho) = \sum_k \langle e_k | U (\rho \otimes |0\rangle \langle 0|) U^\dagger | e_k \rangle = \sum_j E_j \rho E_j^\dagger,
$$

(8)

where $U$ is the unitary operator representing the free evolution of the system, reservoir, as well as the interaction between the two, $|0\rangle$ is the environment’s initial state, and $\{|e_k\}$ is a basis for the environment. The environment and the system are assumed to start in a product state. The $E_j \equiv \langle e_k | U |0\rangle$ are the Kraus operators, which satisfy the completeness condition $\sum_j E_j^\dagger E_j = I$. It can be shown that any transformation that can be cast in the form (8) is a CP map \[3\].

There are infinitely many Kraus operator representations even within the same representation basis of the system, depending on the choice of tracing basis $\{|e_k\}$ of the environment. Each of these sets of Kraus operators is unitarily related to the other: let $E_k = \langle e_k | U |0\rangle$ and $E'_k = (e'_k | U |0\rangle$. Define unitary operation $V$ such that $\langle e'_k | = \langle e_k | V^\dagger$, and hence $E'_k = \langle e_k | V^\dagger U |0\rangle$. Now $V|e_k\rangle = \sum_j \alpha_{jk} |e_j\rangle$ and thus

$$
E'_k = \langle e_k | V^\dagger U |0\rangle = \sum_j \alpha_{jk}^* \langle e_j | U |0\rangle = \sum_j \alpha_{jk}^* E_j.
$$

(9)

The above can be represented as a matrix-valued vector equation

$$
\mathcal{E} \vec{E}_k = V^\dagger \vec{E}_k.
$$

(10)

Let $\vec{A} = (A_i)$ and $\vec{B} = (B_i)$ where $A_i$ and $B_i$ are $d \times d$ matrices (here Kraus operators) and $i = 1, 2, \ldots, d^2$. 
Consider the transformation of the matrix-valued inner product between $\vec{A}$ and $\vec{B}$.

$$\vec{A}^\top \vec{B} = \sum_i (\hat{A}_i^\dagger \hat{B}_i') = \sum_{ijk} (U_{ij} \hat{A}_j^\dagger) U_{ik} \hat{B}_k = \sum_j \hat{A}_j^\dagger U_{jk} \hat{B}_k = \sum_j \hat{A}_j^\dagger \delta_{jk} \hat{B}_k = \sum_j \hat{A}_j^\dagger \hat{B}_j.$$

(11)

As a corollary, the Hilbert-Schmidt product of any two Kraus ‘vectors’, $\sum_j \text{Tr}(\hat{A}_j^\dagger \hat{B}_j)$ is preserved.

Consider the vector obtained by reading off a fixed element, say element of index $lm$, namely, $(E_j)_{lm}$, for each Kraus operator. Eq. (10) can be thought of as applying a unitary transformation to $d^2$ (not necessarily independent) such vectors. Thus one can define a host of other norms that are preserved under this transformation. Any channel parameter (such as gate fidelity, etc.) must be a function of such a generalized norm in order to be unitarily invariant under the transformation Eq. (10) and thus be a valid measure to characterize channel performance. For example, the quantity $\sum_j |\text{Tr}(E_j)|^2$ is another acceptable norm.

The Kraus operators $K_j$ obtained by the Choi method satisfy the orthogonality condition $\text{Tr}(E_j^\dagger E_k) = 0$ for $j \neq k$, which is not a unitarily invariant condition. In particular, the Kraus operators for the SGAD channel obtained in Ref. [15] lack this form.

The SGAD channel derived here is typical of dissipative channels [17], which are characterized by the non-commutativity of the interaction Hamiltonian $H_{SR}$ and the system Hamiltonian $H_S$. By contrast, the QND case, where these two do commute, is marked by pure phase damping and no dissipation, i.e., populations remain unchanged. Here we show that the condition $[H_S, H_{SR}] = 0$ implies the commutativity of the Kraus operators and quantum states used for communication (the signal states), assumed to be eigenstates of $H_S$ and $H_{SR}$. Let $|e\rangle$ be the initial state of the environment (which may be generalized to a separable mixed state) and $\{\{e_j\}\}$ an environmental basis.

For arbitrary non-dissipative interaction, we take: $H_{SR} = \sum_k \alpha_k |k\rangle \langle k| \otimes \hat{P}$, where $\{\{k\}\}$ is a basis for the first particle and $\hat{P}$ an environmental observable. Given $H = H_S + H_R + H_{SR}$, with $H_S = \sum_k \lambda_k |k\rangle \langle k|$ and $H_R = f(\hat{P})$, we have:

$$E_j = \langle e_j | e^{iHt} | e\rangle = \langle e_j | e^{i\sum \lambda_k |k\rangle \langle k| \otimes \hat{P} t} | e'\rangle = \langle e_j | \sum_k |k\rangle \langle k| \otimes e^{i(\lambda_k + \alpha_k \hat{P} t)} | e'\rangle = \sum_k |k\rangle \langle k| \beta_k^{(j)},$$

(12)

where $\beta_k^{(j)} = \langle e_j | e^{i(\lambda_k + \alpha_k \hat{P} t)} | e'\rangle$ and $|e'\rangle = e^{i\int \hat{P}} |e\rangle$. If the eigenstates of the system Hamiltonian, denoted $\{|k\}\}$, are taken to be the signal states, then the statement that $[|k\rangle \langle k|, E_j] = 0$ is equivalent to $[H_S, H_{SR}] = 0$. If the signal states do not commute with Kraus operators, then $[H_S, H_{SR}] \neq 0$, and the system-environmental interaction must be dissipative. This is a unitarily invariant feature since the condition $[H_S, H_{SR}] = 0$ is independent of the tracing basis used to determine the Kraus operators.
IV. CANONICAL KRAUS REPRESENTATION OF THE SGAD CHANNEL

The action of the SGAD channel on the single qubit state $\rho$, denoted $\mathcal{E}$, is given by\cite{15}:

$$
\langle \sigma_x(t) \rangle = [1 + \frac{1}{2}(e^{\gamma_0 a t} - 1)(1 + \cos(\Phi))][e^{-\gamma_0(2N+1)t/2}] \langle \sigma_x(0) \rangle - \sin(\Phi) \sinh(\frac{\gamma_0 a t}{2})[e^{-\gamma_0(2N+1)t/2}] \langle \sigma_y(0) \rangle

\equiv A\langle \sigma_x(0) \rangle - B\langle \sigma_y(0) \rangle,
$$

$$
\langle \sigma_y(t) \rangle = [1 + \frac{1}{2}(e^{\gamma_0 a t} - 1)(1 - \cos(\Phi))][e^{-\gamma_0(2N+1)t/2}] \langle \sigma_y(0) \rangle - \sin(\Phi) \sinh(\frac{\gamma_0 a t}{2})[e^{-\gamma_0(2N+1)t/2}] \langle \sigma_x(0) \rangle

\equiv G\langle \sigma_y(0) \rangle - B\langle \sigma_x(0) \rangle,
$$

$$
\langle \sigma_z(t) \rangle = e^{-\gamma_0(2N+1)t/2} \langle \sigma_z(0) \rangle - \frac{1 - e^{-\gamma_0(2N+1)t}}{2N+1} \equiv H \langle \sigma_z(0) \rangle - Y. \tag{13}
$$

Here $\gamma_0$, $r$, $\Phi$ are as defined in Eq. (7) and $a = \sinh(2r)/(2N_{th} + 1)$.

Consider the maximally entangled (unnormalized) state $|\tilde{\psi}\rangle = (|00\rangle + |11\rangle)$. We find, using Eq. (13), the Choi matrix

$$
C_{\mathcal{E}} \equiv (I \otimes E)|\tilde{\psi}\rangle\langle \tilde{\psi}| = 
\begin{pmatrix}
(1 + H - Y)/2 & 0 & 0 & \frac{A + G}{2} \\
0 & (1 - H + Y)/2 & \frac{A - G}{2} + iB & 0 \\
0 & \frac{A - G}{2} - iB & (1 - H - Y)/2 & 0 \\
\frac{A + G}{2} & 0 & 0 & (1 + H + Y)/2
\end{pmatrix} \tag{14}
$$

According to Choi's theorem, the $d^2$ Kraus operators can be constructed by 'squaring' (juxtaposing $d$-element long column segments of) the eigenvectors of $C_{\mathcal{E}}$, which have been normalized to their eigenvalues \cite{12}. They can be shown to be:

$$
J_{\pm} = \frac{1}{M_\pm} \begin{pmatrix} 0 & \sqrt{1 - H \mp \Psi} \\ \frac{\sqrt{1 - H \pm \Psi}}{2B + i(A - A)} & 0 \end{pmatrix},
$$

$$
K_{\pm} = \frac{1}{N_\pm} \begin{pmatrix} -\sqrt{1 + H \pm \eta} & 0 \\ \frac{\sqrt{1 + H \mp \eta}}{A + G} & 0 \end{pmatrix}, \tag{15}
$$

where $\Psi = \sqrt{(A - G)^2 + 4B^2 + Y^2}$, $\eta = \sqrt{(A + G)^2 + Y^2}$, and $M_\pm = \sqrt{2} \sqrt{1 + \left| \frac{\mp Y + \Psi}{2B + i(A - A)} \right|^2}$, $N_\pm = \sqrt{2} \sqrt{1 + \left| \frac{Y + \eta}{A + G} \right|^2}$.

The Kraus operators for the noise process, generated by the SGAD channel, were derived in Ref. \cite{15}, using an ansatz based on a standard operator-sum representation \cite{13}. As illustrated by the Eq. (10), a necessary and sufficient condition for the equivalence of two different Kraus operator representations is that they are related by a unitary transformation. We demonstrate this for the SGAD channel by finding the unitary transformation connecting the Kraus operators derived via Choi formalism, Eqs. (15), and those derived in Ref. \cite{15}, which we denote $J'_{\pm}$ and $K'_{\pm}$. Writing

$$
\begin{pmatrix} J'_+ \\ J'_- \\ K'_+ \\ K'_-
\end{pmatrix} = U \begin{pmatrix} J_+ \\ J_- \\ K_+ \\ K_-
\end{pmatrix}, \tag{16}
$$

we find that

$$
U = \begin{pmatrix} 0 & \Upsilon_+ & 0 & \Upsilon''_+ \\ \Upsilon_- & 0 & 0 & \Upsilon''_- \\ \Upsilon'_+ & 0 & \Upsilon'_+ & 0 \\ \Upsilon'_- & 0 & \Upsilon'_- & 0
\end{pmatrix}, \tag{17}
$$

where \( \Upsilon \) and \( \Upsilon'' \) are given by the expressions in Eq. (10).
Given any set of points $x_i \in S$, if the convex combination $x = \sum_i \mu_i x_i \in S$, where $\mu_i \geq 0$ and $\sum_i \mu_i = 1$, then the set $S$ is convex. A point $x$ is said to be pure or extreme if it cannot be expressed as a (non-trivial) convex combination two or more points. The smallest convex set $H$ that contains a given set $S$ is the convex hull of $S$. The convex hull of a given finite number of pure points is a convex polytope. Geometrically, a polytope can be visualized as an object or tile with flat sides. In the space of dimension $n$, the convex hull of $n + 1$ points that are not confined to an $n - 1$ dimensional subspace is an $n$-simplex, $\Xi_n$. The dimension of a given convex set $S$ is the largest integer $n$, such that $\Xi_n \subseteq S$.

### V. GEOMETRIC STRUCTURE OF CHANNELS

Given any map $\Phi$ that maps the algebra of $m \times m$ complex matrices to another matrix algebra, we may define the rank of the channel as that of the matrix associated with $\Phi$ [36]. Here, by virtue of the Choi isomorphism, one may associate a rank with the channel, identified with that of the corresponding Choi matrix. For the SGAD channel, the eigenvalues of the Choi matrix are given by

$$e_\pm = \frac{1}{2} \left( 1 - H \pm \sqrt{(A - G)^2 + 4B^2 + Y^2} \right),$$

$$f_\pm = \frac{1}{2} \left( 1 + H \pm \sqrt{(A + G)^2 + Y^2} \right).$$

Clearly, $e_+ \geq e_-$ and $f_+ \geq f_-$. The trivial case corresponds to the unitary channel, wherein channel parameters $T = r = 0$, and $f_+ = 1$ with all other eigenvalues equal to zero. Let us consider a nontrivial noise where $e_- = 0$ for a given channel. From Eq. (19), it follows that $1 - H = \sqrt{(A - G)^2 + 4B^2 + Y^2}$. This, as can be seen from Eq. (13), is equivalent to $r = T = 0$, which in turn implies that $1 + H = \sqrt{(A + G)^2 + Y^2}$ and therefore that $f_- = 0$. Conversely, it can be shown that $f_- = 0 \implies e_- = 0$. One way to understand this is to note that Eq. (6) that generates the SGAD channel $\mathcal{E}$ has only one Lindblad operator when $T = 0$, and two when $T > 0$.

We thus find that $e_-$ and $f_-$ simultaneously vanish (in the case of unitary and amplitude damping channels with vanishing $T$ and $r$) or both are non-vanishing (for more general channels). For the SGAD channel for a qubit, we thus find that the rank is either 2 or 4. This of course is not a general quantum feature, and noise channels for qubits exist with odd rank greater than 1. An example of a rank 3 channel is the Pauli channel with Kraus operator elements $I, \sigma_x$ and $\sigma_y$ with weights $p, q$ and $r$, where $p + q + r = 1$. For this the Choi matrix is given by:

$$\frac{1}{2} \begin{pmatrix}
 p & 0 & 0 & p \\
 0 & q + r & q - r & 0 \\
 0 & q - r & q + r & 0 \\
 p & 0 & 0 & p
\end{pmatrix},$$

which is manifestly of rank 3 (in that precisely 3 rows are linearly independent).
B. Pauli and depolarizing channels

Under the above isomorphism, the set of unitaries on a qudit maps to pure states in $V$, the set of two-qudit states isomorphic to CP maps on a single qudit. The general state of a two-qubit density operator is given by:

$$\rho = \frac{1}{4} \left( I \otimes I + \sum_j r_j \sigma_j \otimes I_2 + s_j I_2 \otimes \sigma_j + \sum_{j,k} t_{j,k} \sigma_j \otimes \sigma_k \right),$$

(21)

where $r_j, s_j$ and the tensor $t_{j,k}$ are generally complex numbers subject to requirement $\rho = \rho^\dagger$ and $\text{Tr}(\rho) = 1$. Letting $|\psi\rangle = \frac{1}{\sqrt{2}} (|00\rangle + |11\rangle)$, we have

$$|\psi\langle\psi| = \frac{1}{4} (I \otimes I + \sigma_x \otimes \sigma_x - \sigma_y \otimes \sigma_y + \sigma_z \otimes \sigma_z) = (E_X \otimes I)|\psi\langle\psi| \equiv I,$$

(22)

where $E_Z$ is the trivial noise, corresponding to the identity operator. Under the Choi isomorphism the corresponding state is therefore $I$.

In this Section, for two-qubit states which have only the $I \otimes I$ and the $t_{j,j}$ components non-vanishing, we will represent $\rho$ by its signature, the list of these components multiplied by 4. Thus, $I \equiv (1,1,1,1)$. More generally, the class of states we consider in this subsection have the signature $(\alpha,\beta, \gamma, \delta)$, and are characterized by the (quadratic) mixedness $d = (1 - \text{Tr}(\rho^2)) = 1 - |a|^2 + |b|^2 + |c|^2$.\(^3\)

Consider the phase flip quantum channel represented by the set of Kraus operators $[\sqrt{\alpha}I, \sqrt{1-\alpha}Z]$, where $Z$ stands for the Pauli operator $\sigma_z$ and $\alpha$ is a real positive number such that $0 \leq \alpha \leq 1$. The state isomorphic to the channel corresponding to application of $Z$ is $Z \equiv (E_Z \otimes I)|\psi\langle\psi| = (1,-1,1,1)$. Thus the phase flip channel is given by the 1-simplex, $F$:

$$\alpha I + (1-\alpha)Z = (0,0,0,1) + (2\alpha - 1)(0,1,-1,0).$$

(23)

It is closely related to the phase damping channel, given by the set of Kraus-operators: $[\sqrt{\alpha}I, \sqrt{1-\beta}P_0, \sqrt{1-\beta}P_1]$, where $P_0 = |0\rangle\langle 0|$ and $P_1 = |1\rangle\langle 1|$ are projectors and $\beta$ is a real positive number such that $0 \leq \beta \leq 1$. By the Choi isomorphism, they correspond to states: $I$ and $Z \equiv (E_P \otimes I)|\tilde{\psi}\langle\tilde{\psi}| = (1,0,0,1)$. The phase damping channel is given by the 1-simplex

$$\beta I + (1-\beta)Z = (0,0,0,1) + (2\alpha - 1)(0,1,-1,0).$$

(24)

Comparing this with Eq. (23), it is seen that the phase damping channel is strictly a subset of the phase flip channel. In particular, the phase damping channel extreme point obtained with $\beta = 0$ corresponds to the mixed point of the phase flip channel given by $\alpha = \frac{1}{2}$. The former corresponds to the latter in the range $\alpha \in [\frac{1}{2}, 0]$, where they are related according to $\beta = 2\alpha - 1$.

The generalised depolarising or Pauli channels have Pauli operators (apart from a factor) as their Kraus operators, i.e., $[\sqrt{\alpha}I, \sqrt{\beta}X, \sqrt{\gamma}Y, \sqrt{\delta}Z]$, where $\alpha, \beta, \gamma, \delta \geq 0$ are real numbers satisfying $\alpha + \beta + \gamma + \delta = 1$. We define $\mathcal{X} \equiv (E_X \otimes I)|\tilde{\psi}\langle\tilde{\psi}| = (1,1,1,1)$ and $\mathcal{Y} \equiv (E_Y \otimes I)|\tilde{\psi}\langle\tilde{\psi}| = (1,-1,-1,1)$. Thus every Pauli channel is a member of the polytope given by four pure points $I, X, Y, Z$, as

$$v = \alpha I + \beta X + \gamma Y + \delta Z = (1, \alpha + \beta - \gamma - \delta, -\alpha + \beta - \gamma + \delta, \alpha - \beta - \gamma + \delta).$$

(25)

It follows from the properties of vector spaces that if $I, X, Y, Z$ are mutually orthogonal, then the decomposition is indeed unique. It is readily seen that six inner products between these elements, given by the Hilbert-Schmidt product $\text{Tr}(I X)$, $\text{Tr}(Y X)$, etc., indeed vanish. Thus the set of all Pauli channels, the polytope $\mathcal{P}$, is a 3-simplex (a tetrahedron) embedded within $V$. The phase flip channel $\mathcal{F}$ corresponds to a proper subset of $\mathcal{P}$, in particular, the edge $(I, Z)$ of the latter, and the volume of phase damping channels in this set is $\frac{1}{2}$. This structure has been studied using affine maps on Bloch sphere in Ref. 37, where it was shown that the fraction of the channels that can be simulated with a one-qubit environment is $\frac{3}{2}$. The elements of the important, depolarizing channel are characterized by the action:

$$\rho \mapsto p \rho + (1-p) \frac{I}{2},$$

(26)
Noting that since for any $\rho$, $\frac{1}{4}(\rho + \sigma_x \rho \sigma_x + \sigma_y \rho \sigma_y + \sigma_z \rho \sigma_z)$, Eq. (20) is seen to have a Kraus representation
\[
\begin{bmatrix}
\sqrt{\frac{1+3p}{4}} I, \\
\sqrt{\frac{1-(1-p)}{4}} \sigma_x, \\
\sqrt{\frac{1-(1-p)}{4}} \sigma_y, \\
\sqrt{\frac{1-(1-p)}{4}} \sigma_z
\end{bmatrix}.
\]
The Choi matrix for this process has the convex structure:
\[
V = pI + \frac{(1-p)}{4} (I + X + Y + Z) \quad (0 \leq p \leq 1)
\]
\[
= (1, p, -p, p), \quad (27)
\]
which is just the two-qubit Werner state $pI \otimes I + (1-p)|\tilde{\psi}\rangle\langle\tilde{\psi}|$.

The twirling operation [8] on states is defined by:
\[
T(\rho) = \int dU \otimes U^* \rho U \otimes U^*.
\]
While it leaves a single state invariant, it maps an arbitrary two-qubit state to a Werner state. Interpreted as an operation on maps, it maps any channel to the depolarizing channel. It can be shown to have the property that the fidelity $F = F(|\psi\rangle, (I \otimes E)|\psi\rangle\langle\psi|)$ is preserved. Under the Choi isomorphism, this is a contractive CP map collapsing arbitrary points in the above Pauli 3-simplex into points in the depolarizing simplex.

For the depolarizing channels, representing Werner family of states $\phi_D(p) = (1, p - p, \bar{p})$, one finds $F = \frac{3p + 1}{4}$, while for the Pauli channel, represented by the state $\phi_P(\alpha, \beta, \gamma) = (1, \alpha + \beta - \gamma - \delta, -\alpha + \beta + \gamma + \delta, \alpha - \beta - \gamma + \delta)$, one finds $F = \alpha$, independent of $\beta, \gamma, \delta$. From the property of preservation of $F$ under twirling, it follows $\phi_P$ is twirled to $\phi_D = (1, \frac{4\alpha - 1}{3}, -\frac{4\alpha - 1}{3}, \frac{4\alpha - 1}{3})$.

It follows from Eq. (27) that $V = \alpha I + (1 - \alpha) D$ with, $(\frac{1}{3} \leq p \leq 1)$, where $D = (X + Y + Z)/3$ and $\alpha = (3p + 1)/4$. The set $D$ of all depolarizing channels forms a 1-simplex embedded within $\mathcal{P}$, suspended from $I$ towards the $X + Y + Z$ base of the tetrahedron, but terminating above the base at the point $\frac{1}{3}(I + X + Y + Z)$.

C. The SGAD channel

The Choi matrix for the generalized amplitude damping channel (the SGAD channel with squeezing set to zero) can be obtained from the Kraus operators:
\[
\begin{align*}
E_1 &\equiv \sqrt{p} \begin{bmatrix}
\sqrt{1 - \alpha} & 0 \\
0 & 1
\end{bmatrix}; & E_2 &\equiv \sqrt{\bar{p}} \begin{bmatrix}
0 & 0 \\
\bar{\alpha} & 0
\end{bmatrix}; \\
E_3 &\equiv \sqrt{1 - p} \begin{bmatrix}
\sqrt{1 - \mu} & 0 \\
0 & \sqrt{1 - \nu}
\end{bmatrix}; & E_4 &\equiv \sqrt{1 - p} \begin{bmatrix}
0 & \sqrt{\mu e^{-i\phi}} \\
\bar{\nu} & 0
\end{bmatrix},
\end{align*}
\]
where $0 \leq p \leq 1$ [5][13].

The two corresponding Choi matrices, with Kraus operators $E_{1,2}$ and $E_{3,4}$, respectively, are:
\[
(\mathcal{E}_{12} \otimes I)|\tilde{\psi}\rangle\langle\tilde{\psi}| = \frac{1}{4} \left(I \otimes I - \sigma_z \otimes I + \sqrt{1 - \alpha \sigma_x \otimes \sigma_x} - \sqrt{1 - \alpha \sigma_y \otimes \sigma_y} + (1 - \alpha) \sigma_z \otimes \sigma_z \right),
\]
\[
(\mathcal{E}_{34} \otimes I)|\tilde{\psi}\rangle\langle\tilde{\psi}| = \frac{1}{4} \left(I \otimes I + (\nu - \mu) \sigma_z \otimes I + (\sqrt{1 - \mu} (1 - \nu + \sqrt{\mu} \cos(\phi) \sigma_x \otimes \sigma_x - \sqrt{\mu} \sin(\phi) \sigma_y \otimes \sigma_y) - (1 - \nu + \sqrt{\mu} \cos(\phi) \sigma_y \otimes \sigma_y + \sqrt{\mu} \sin(\phi) \sigma_x \otimes \sigma_x) \right).
\]

It would seem from this that the generalized amplitude damping channel (and by extension SGAD), has the convex structure
\[
\Lambda = p\mathcal{E}_{12} + (1 - p)\mathcal{E}_{34},
\]
where the extreme points are given by amplitude damping channels.

However, this turns out not to be the case because the $p$ in Eq. (31) is also a function of channel parameters that determine the extreme points. Thus, varying the ‘convex’ parameter $p$ shifts the extreme points. The rather complicated relationship between $p$ and $\alpha, \nu, \mu$ is given in Ref. [13]. However, this functional dependence of the convex parameter on channel properties implies the following result.

Theorem 1 The set of all SGAD channels is not convex.
**Proof.** Assume that Eq. (31) defines a valid convex set in the model for arbitrary \( p \) in the range \([0, 1]\). The channel parameters are temperature, squeezing, etc., which may be denoted \( x_i \) (for \( 1 \leq i \leq N \), for any finite \( N \)). Since \( p = p(x_i) \), each possible choice of \( p \) constitutes a constraint to be satisfied while keeping fixed the extreme points which are also functions of \( x_i \). Clearly, this is impossible to satisfy for any finite \( N \).  

It is an interesting question how the locus of the extreme points as a function of \( p \) relates to the general theory of area preserving canonical transformations.

Since all unitary operations are mapped to pure (maximally entangled) Choi matrices, mixedness of the latter implies decoherence in the channel. This suggests that the degree of decoherence can be quantified by the amount of mixedness of the Choi matrix, \( C_E \), Eq. (14), Ref. [38].

\[
S = -\text{Tr}[C_E \log_2 C_E].
\] (32)

Likewise, since the noise acting on one of the states will lead to a reduction in correlation between the two states, the degree of separableness of the Choi matrix also can be considered as a quantification of channel decoherence. An appropriate measure of entanglement is concurrence [39]:

\[
\mathcal{L} = \max\{0, \lambda_1 - \lambda_2 - \lambda_3 - \lambda_4\}
\] (33)

where \( \lambda_1, \lambda_2, \lambda_3, \lambda_4 \) are the eigenvalues of \((\sigma_y \otimes \sigma_y)C_E(\sigma_y \otimes \sigma_y)^T\) arranged in decreasing order.

As a quick illustration, for a phase flip channel given by Kraus operator elements \( \{\sqrt{p}I, \sqrt{1-p}Z\} \) (0 \( \leq p \leq \frac{1}{2} \), it is easily seen that the von Neumann entropy of the Choi matrix is given by \( H(p) \), the Shannon entropy, and the concurrence by \( 1 - 2p \). Thus we find that as the noise level is increased, so does the degree of mixedness and the separability of the Choi matrix. In Figures 1(a) and 1(b), we plot the von Neumann entropy and concurrence, respectively, of the Choi matrix subjected to a SGAD channel. As expected we find that they indicate an increase of decoherence under increase of \( T \). However, there are regions where squeezing appears to suppress decoherence, as seen from the Figure 1(a) near \( T = 1 \).

![Figure 1](image-url)

**FIG. 1:** Two possible quantifications of the decoherence due to the action of a SGAD channel, as function of temperature (\( T \)) and squeezing, parametrized by \( r \), with time \( t = 0.5 \), frequency \( \omega = 0.01 \), bath parameter \( \gamma_0 = 0.1 \) and squeezing angle \( \Phi = 0.3 \) (in the units where \( \hbar = k_B = 1 \)).

### VI. GATE AND CHANNEL Fidelities

We here characterize the performance of the SGAD channel in terms of parameters which, as noted earlier, should be unitarily invariant. One such quantity is the gate fidelity [40]

\[
g = \max_\rho F(\rho, E(\rho)),
\] (34)
FIG. 2: SGAD channel properties, as function of temperature ($T$) and squeezing, parametrized by $r$, with time $t = 0.5$, frequency $\omega = 0.01$, bath parameter $\gamma_0 = 0.1$ and squeezing angle $\Phi = 0.3$ for (a) and $\Phi = 0.0$ for (b) (in the units where $\hbar = k_B = 1$). Both quantities show a counter-intuitive rise with squeezing.

the fidelity of a state with its noisy version, maximized over all states, where fidelity $F(\rho, \sigma) = \sqrt{\rho \sigma \rho}$. Intuitively it represents how well a gate performs the operation it is supposed to implement. Another is the average gate fidelity $g_{\text{av}}$: 

$$g_{\text{av}} = \int_{\rho} F(\rho, \mathcal{E}(\rho)) \omega(\rho) d\rho,$$

where $\omega$ is a suitable uniform measure over state space. A closed analytic expression exists for this, due to Ref. [8], given by

$$g_{\text{av}} = d + \sum_i |\text{Tr}(E_i)|^2 d(d+1).$$

(36)

Another similar parameter is teleportation distance [10].

A related parameter, introduced in Ref. [15], is channel fidelity, which is a measure of how well a gate preserves the distinguishability of states:

$$\kappa \equiv \max_{\mathcal{B}} \chi(\mathcal{B}, \mathcal{E}),$$

(37)

where $\chi(\mathcal{B}, \mathcal{E})$ is the Holevo bound for a state prepared in basis elements of basis $\mathcal{B}$, subjected to noise $\mathcal{E}$. Thus $\kappa$ maximizes the distinguishability (quantified by the Holevo bound) over all possible bases (sets of orthonormal states). Clearly $\kappa \leq C_1 \leq C$, where $C_1$ is the product state channel capacity, and $C$, the channel capacity maximized over $n$-fold entanglement ($n \to \infty$) [43].

$\kappa$ manifestly possesses unitary invariance because it is computed from the density operator directly, and is thus independent of the tracing basis used to obtain the Kraus operators. Although currently no known closed expression exists for channel fidelity, we expect that its behavior should be similar to that of gate fidelity, at least qualitatively. This expectation is supported in a comparison of the effect of temperate and squeezing on them, as discussed below.

A plot of $g_{\text{av}}$ for the SGAD channel is given in Figure (2(a)). While at low enough temperature, squeezing reduces average gate fidelity $g_{\text{av}}$, a range of temperature is seen to exist, in which squeezing causes an increase in the quantity. A similar counter-intuitive reduction of $\kappa$ with squeezing is depicted in Figure 2(b).

What is remarkable is that even in regimes where noise increases, as indicated by Figures 1(a), 1(b) and 2(a), obtained by increasing squeezing at fixed temperature, the distinguishability of initially orthogonal states, as given by channel fidelity in Figure 2(b), increases. We confirmed this behavior by employing the trace distance measure instead of channel fidelity, obtaining the same pattern. It follows that in this signaling ensemble, inspite of the diffusion caused by noise, the initially orthogonal states continue to enjoy a nearly orthogonal support. Invariably, this feature happens only when the increase in decoherence is due to increase in squeezing $r$ at a given temperature.
VII. DISCUSSIONS AND CONCLUSIONS

Single-qubit channels have been studied under the two broad classes of AD and generalized depolarizing channels, which are fairly exhaustive in real life situations. Two of the authors had earlier derived [15] an operator sum representation of the SGAD channel, by generalizing the GAD channel. A different derivation, that exploits the Choi channel state isomorphism was presented here, along with the unitary operation relating it to the previous derivation.

There is a rich structure to be explored by the isomorphism. As a small part of larger work that may be undertaken here, we characterize the difference in the geometry and rank of these channel classes. The degree of decoherence of the qubit channel is quantified according to the amount of mixedness, as quantified by the von Neumann entropy, or separability, quantified by the absence of concurrence, of the Choi matrix.

Whereas the generalized depolarizing channels possess a convex structure and form a 3-simplex, the AD class channels lack a convex set as seen from an ab initio perspective, and are thus more complicated to study. Further, where the rank of generalized depolarizing channels can be any positive integer up to 4, that of amplitude damping ones is either 2 or 4. Various channel performance parameters can be used to bring out the different influences of temperature and squeezing in dissipative channels. In particular, a noise range in terms of $r$ and $T$ was identified where initially orthogonal states prepared in a suitable basis can become more distinguishable inspite of decohering. This happens only when squeezing is increased, rather than temperature.
