Abstract

A measurement of the rate for the “wrong-sign” decay $D^0 \rightarrow K^+\pi^-\pi^+\pi^-$ relative to that for the “right-sign” decay $D^0 \rightarrow K^-\pi^+\pi^+\pi^-$ is presented. Using 791 fb$^{-1}$ of data collected with the Belle detector, we obtain a branching fraction ratio of $R_{ws} = [0.324 \pm 0.008({\text{stat}}.) \pm 0.007({\text{sys}}.)\%]$. Multiplying this ratio by the world average value for the branching fraction $B(D^0 \rightarrow K^-\pi^+\pi^+\pi^-)$ gives a branching fraction $B(D^0 \rightarrow K^+\pi^-\pi^+\pi^-) = (2.61 \pm 0.06^{+0.09}_{-0.08}) \times 10^{-4}$.
Studies of mixing in neutral meson systems have had an important impact on the development of the Standard Model. Historically, mixing was first observed in the $K^0\overline{K}^0$ system [1], then later in the $B^0\overline{B}^0$ system [2], and most recently in the $B_s^0\overline{B}_s^0$ [3] and $D^0\overline{D}^0$ systems [4–6]. Mixing in the $D^0\overline{D}^0$ system is strongly suppressed due to Cabibbo-Kobayashi-Maskawa (CKM) matrix elements and the GIM mechanism [7]. It has been measured using several methods [9], one of which compares the time-dependence of “wrong-sign” $D^0 \rightarrow K^+\pi^- (X)$ decays to that of “right-sign” $D^0 \rightarrow K^-\pi^+ (X)$ decays [5, 6, 10–12]. Wrong-sign decays can occur either via a doubly Cabibbo-suppressed (DCS) amplitude such as $D^0 \rightarrow K^+\pi^-\pi^+\pi^-$ or via $D^0$ mixing to $\overline{D}^0$, followed by a Cabibbo-favored (CF) decay such as $\overline{D}^0 \rightarrow K^+\pi^- (X)$.

In this report we present a measurement for the rate of the wrong-sign (WS) decay $D^0 \rightarrow K^+\pi^-\pi^+\pi^-$ relative to that of the right-sign (RS) decay $D^0 \rightarrow K^-\pi^+\pi^+\pi^-$ using a data sample of 791 fb$^{-1}$ [13]. Assuming negligible $CP$ violation, the ratio of decay rates can be expressed as [14]

$$R_{ws} \equiv \frac{\Gamma(D^0 \rightarrow K^+\pi^-\pi^+\pi^-)}{\Gamma(D^0 \rightarrow K^-\pi^+\pi^+\pi^-)} = R_D + \alpha y' \sqrt{R_D} + \frac{1}{2}(x'^2 + y'^2),$$  

where $R_D$ is the squared magnitude of the ratio of the DCS to CF amplitudes, $\alpha$ is a suppression factor that accounts for strong-phase variation over the phase space ($0 \leq \alpha \leq 1$) [11], and $x'$ and $y'$ are the mixing parameters $x \equiv \Delta m/\Gamma$ and $y \equiv \Delta\Gamma/2\Gamma$ rotated by the effective strong phase difference $\delta$ between DCS and CF amplitudes: $x' = x\cos\delta + y\sin\delta$ and $y' = y\cos\delta - x\sin\delta$. The parameters $x$ and $y$ depend only on the mass difference $(\Delta M)$ and decay width difference $(\Delta\Gamma)$ between the $D^0$-$\overline{D}^0$ mass eigenstates, and the mean decay width $(\Gamma)$. The Belle collaboration has previously measured $R_{ws} = [0.320 \pm 0.018 (\text{stat.})^{+0.018}_{-0.013} (\text{sys.})]\%$ [15]. The measurement presented here supersedes this previous result. We use an improved reconstruction code that has a higher reconstruction efficiency for low momentum tracks. The data used in this analysis corresponds to an integrated luminosity of 791 fb$^{-1}$ collected at or near the $\Upsilon(4S)$ resonance.

The data sample was collected by the Belle detector [16] located at the KEKB asymmetric-energy $e^+e^-$ collider [17]. The Belle detector is a large-solid-angle magnetic spectrometer consisting of a silicon vertex detector (SVD), a 50-layer central drift chamber (CDC), an array of aerogel threshold Cherenkov counters (ACC), a barrel-like arrangement of
time-of-flight scintillation counters (TOF), and an electromagnetic calorimeter (ECL) based on CsI(Tl) crystals. These detector elements are located inside a superconducting solenoid coil that provides a 1.5 T magnetic field. Muon identification is provided by an array of resistive plate chambers (KLM) interspersed with iron shielding that is used as the magnetic flux return. For charged hadron identification, a likelihood ratio $L_K \equiv L(K)/(L(K) + L(\pi))$ is formed based on $dE/dx$ measured in the CDC and the response of the ACC and TOF. Charged kaons are identified using a likelihood requirement that is about 86% efficient for $K^\pm$ and has a $\pi^\pm$ misidentification rate of about 8%.

We reconstruct the decay $D^{*\pm} \rightarrow D^0\pi_s^\pm$, $D^0 \rightarrow K^\pm\pi^\pm\pi^\mp\pi^\pm$, in which the charge of the low-momentum (or “slow”) pion $\pi_s^\pm$ identifies the flavor of the neutral $D$ candidate. For each event, the $D^0 \rightarrow K^\pm\pi^\pm\pi^\mp\pi^\pm$ candidate is formed from combinations of four charged tracks. We require that the likelihood ratio $L_K$ be greater than 0.7 for kaons and less than 0.4 for pions. All track candidates are required to have a distance-of-closest-approach of less than 5.0 cm along the $z$ axis. In the transverse $r$-$\phi$ plane, we require a distance-of-closest-approach of less than 2.0 cm for pion candidates and less than 1.0 cm for kaon candidates. To suppress backgrounds from semileptonic decays, we reject tracks satisfying electron or muon identification criteria based on information from the ECL and KLM detectors. This veto has an efficiency of 95% for signal events and reduces the number of electron (muon) background events by 93% (95%). We require that each track used to reconstruct the $D^0$ have at least two SVD hits in both the $r$-$\phi$ and $z$ coordinates. We retain events having a $K\pi\pi\pi$ invariant mass ($M_{K3\pi}$) satisfying $1.81 \text{ GeV}/c^2 < M_{K3\pi} < 1.92 \text{ GeV}/c^2$.

For $D^0 \rightarrow K^+\pi^-\pi^+\pi^-$, when the momenta of a daughter kaon and pion are similar, their masses can be exchanged without a significant effect upon $M_{K3\pi}$. This misidentification leads to “feed-through” background from RS $D^0 \rightarrow K^-\pi^+\pi^+\pi^-$ decays in the WS sample. To suppress this background, we recalculate $M_{K3\pi}$ of WS candidates after swapping the kaon and pion mass assignments and reject events in which $|M_{K3\pi}(\text{swapped}) - m_{D^0}| < 20 \text{ GeV}/c^2$. From Monte Carlo (MC) simulation, we find that this veto has a signal efficiency of 92% while rejecting 94% of this background.

To suppress backgrounds from the singly Cabibbo-suppressed decay $D^0 \rightarrow K_S^0 K^+\pi^-$ followed by $K_S^0 \rightarrow \pi^+\pi^-$, we veto events in which either of the $\pi^+\pi^-$ daughter combinations has an invariant mass within 20 MeV/$c^2$ (3.3$\sigma$ in resolution) of the $K_S^0$ mass. This veto has an efficiency of 97% for signal events and reduces the number of $K_S^0$ background events in
Monte Carlo by 90%.

To suppress background from random combinations of tracks, the daughter tracks from the $D^0$ candidate are required to originate from a common vertex. To reconstruct the $D^*$ candidate, we perform a vertex fit that constrains the $D^0$ and the $\pi_s$ candidate to the interaction point (IP) of the beams. The resolution on the mass difference $Q \equiv M_{\pi_sK3\pi} - M_{K3\pi} - m_{\pi}$ is significantly improved by this requirement. We require that the $\chi^2$ probability for each vertex fit be greater than 0.1% and that $Q < 10 \text{ MeV}/c^2$. To eliminate $D$ mesons produced in $B\bar{B}$ events, we require that the momentum of the $D^*$ candidate be greater than 2.5 GeV/$c$ in the center-of-mass (CM) frame. After all selection requirements, the fraction of events containing multiple candidates is 8.6%. For these events, we select the candidate that minimizes the sum of $\chi^2$ values divided by the sum of degrees of freedom (d.o.f.), where each sum extends over both vertex fits.

We measure RS and WS signal yields by performing a two-dimensional binned maximum likelihood fit to the $M_{K3\pi}$ and $Q$ distributions. The signal and background probability density functions (PDFs) are determined from MC samples having sizes four times that of the data set. Background PDF shapes are determined separately for RS and WS distributions and fixed in the fit. The backgrounds are divided into four categories: (1) “random $\pi_s$,” in which a CF $D^0 \rightarrow K^- \pi^+ \pi^+ \pi^-$ decay is correctly reconstructed but is subsequently combined with a random slow pion having the WS charge; (2) “broken charm,” in which a true $D^{*+} \rightarrow D^0 \pi^+_s$ decay is combined with a misreconstructed $D^0$; (3) “combinatoric,” consisting of remaining backgrounds from $e^+e^- \rightarrow c\bar{c}$ production; and (4) “uds,” consisting of combinatorial backgrounds from continuum $e^+e^- \rightarrow u\bar{u}, d\bar{d}, s\bar{s}$ production. As no significant correlations are found between $M_{K3\pi}$ and $Q$ for the signal or backgrounds, we model each PDF as the product of one-dimensional functions. Background PDF shapes are parametrized in $Q$ using a threshold function of the form $Q^{1/2} + aQ^{3/2}$ for the random $\pi_s$, combinatoric, and $uds$ components, and a broad Gaussian for the broken charm component. For $M_{K3\pi}$ a second-order Chebyshev polynomial is used for the combinatoric and $uds$ components, and an ARGUS function [18] is used for the broken charm component. For $M_{K3\pi}$ a second-order Chebyshev polynomial is used for the combinatoric and $uds$ components, and an ARGUS function [18] is used for the broken charm component. The random $\pi_s$ background is parametrized in $M_{K3\pi}$ using the same shape as used for the signal (see below). We compare data and MC events in the sideband regions $|Q - 5.865 \text{ MeV}/c^2| > 2.0 \text{ MeV}/c^2$ for numerous kinematic distributions and find good agreement. These distributions include the $D^*$ momentum, the $\chi^2$ value of the vertex fits, particle identification likelihoods, the
cosine of the angle between the $D^0$ and each of its daughter particles, and the momentum of each final state particle. The background normalizations are floated in the fit.

The RS signal PDF is parametrized in $M_{K^3\pi}$ as the sum of one Gaussian and two bifurcated Gaussians with a common mean, and in $Q$ as the sum of a bifurcated Student’s $t$-distribution and a bifurcated Gaussian with common mean. For both distributions, the relative fraction between the single Gaussian and the remaining function(s) is fixed to the value obtained from the MC while all other parameters are floated in the fit. The RS signal PDF is used also for the WS signal PDF. Since the WS and RS samples are fitted simultaneously, the ratio of WS to RS signal yields is extracted directly from the fit. We obtain a RS yield of 990594 ± 1901 events and a “raw” ratio of WS to RS yields of $R'_{\text{WS}} = (0.339 ± 0.008)\%$. This value must be corrected for the ratio of overall efficiencies of RS and WS decays. Projections of the fit are shown in Fig. 1. The fitted RS yield and $R'_{\text{WS}}$ value correspond to a WS yield of 3358 ± 79 events. The goodness of fit is satisfactory: for WS (RS) decays, $\chi^2$/d.o.f. = 1.17 (1.89) for $M_{K^3\pi}$ and 0.90 (1.43) for $Q$.

As $D^0 \to K^+\pi^-\pi^+\pi^-$ and $D^0 \to K^-\pi^+\pi^+\pi^-$ decays proceed largely through intermediate resonances, RS and WS events are expected to have different distributions across the phase space. If the detector acceptance and reconstruction efficiencies vary over phase space, the overall efficiencies for RS and WS decays will differ from each other. The ratio of these efficiencies is needed to correct $R'_{\text{WS}}$.

To obtain the ratio of efficiencies, we divide RS and WS events into 576 bins in a five-dimensional phase space. These dimensions consist of the invariant mass combinations for $K^\pm\pi^\mp$, $K^\pm\pi_1^\mp$, $K^\pm\pi_2^\mp$, $\pi^\pm\pi_1^\mp$, and $\pi^\pm\pi_2^\mp$, where $\pi_1$ and $\pi_2$ label the pions with same sign charge, and $|p_{\pi_1}| > |p_{\pi_2}|$. The binning is chosen to correspond to the structure present in these variables. The efficiency for each bin ($\epsilon_i$) is obtained using MC. We estimate background in the data for bin $i$ by multiplying the total background yield ($N_{\text{bkg}}$) by the fraction of background events in that bin ($f_i$) as obtained from MC simulation. The total background yield is determined from a two-dimensional fit to the $M_{K^3\pi}$-$Q$ distribution of data. The total signal yield is calculated as

$$N'(K\pi\pi\pi) = \sum_{i=1}^{576} \frac{N_i - N_{\text{bkg}} \cdot f_i}{\epsilon_i},$$

where $N_i$ is the number of candidate events in bin $i$. The reconstruction efficiency for either
FIG. 1: Fit projections for $M_{K^3\pi}$ (left) and $Q$ (right). The top (bottom) row shows $D^0 \to K^-\pi^+\pi^+\pi^-$ ($D^0 \to K^+\pi^-\pi^+\pi^-$) candidates. Events plotted for $M_{K^3\pi}$ are required to lie in the signal region for $Q$, and vice versa. The peaking dashed curves show the signal PDF (cyan); the non-peaking dashed curves show broken charm and $uds$ backgrounds (red); the dash-dotted curves include combinatoric backgrounds (green); and the dotted curves include random $\pi_s$ backgrounds (blue). The fit residuals $(N_o - N_p)/\sqrt{N_o}$ are plotted below each fit projection, where $N_o$ ($N_p$) is the observed (predicted) event yield.
\(D^0 \to K^{+}\pi^{-}\pi^{+}\pi^{-}\) or \(D^0 \to K^{-}\pi^{+}\pi^{+}\pi^{-}\) decays is calculated as

\[\epsilon(K\pi\pi) = \frac{1}{N'} \sum_{i=1}^{576} (N_i - N_{\text{bkg}} \cdot f_i),\]

and thus

\[R_{\text{WS}} = \frac{R'_{\text{WS}} \cdot \epsilon(K^{-}\pi^{+}\pi^{+}\pi^{-})}{\epsilon(K^{+}\pi^{-}\pi^{+}\pi^{-})} = \frac{N'(K^{-}\pi^{+}\pi^{+}\pi^{-})}{N'(K^{+}\pi^{-}\pi^{+}\pi^{-})}.\]

Only events located within a signal region \(|m_{K^{3}\pi} - m_{D^0}| < 0.01\) GeV and \(|Q - Q_0| < 0.002\) GeV/\(c^2\) are used to determine the efficiency correction. The efficiency-corrected yields are \(N'(K^{+}\pi^{-}\pi^{+}\pi^{-}) = 37297 \pm 881\) and \(N'(K^{-}\pi^{+}\pi^{+}\pi^{-}) = (1.151 \pm 0.002) \times 10^7\); thus \(R_{\text{WS}} = (0.324 \pm 0.008)\%\).

We consider various sources of systematic uncertainty as listed in Table I. Since we measure the ratio of topologically similar RS and WS decays, many systematic uncertainties cancel.

To determine the systematic uncertainty associated with the ratio of efficiencies, we propagate the statistical errors for \(\epsilon_i\) and \(f_i\) via a Monte Carlo method as follows. We generate values for \(\epsilon_i\) and \(f_i\) in all 576 bins. These values are sampled from Gaussian distributions having mean values equal to the nominal parameter values and standard deviations equal to their uncertainties. We then recalculate \(R_{\text{WS}}\) using these sampled values. We repeat this procedure \(10^5\) times and plot the resulting distribution of \(R_{\text{WS}}\). The RMS of this distribution \((\pm 0.0041)\) is taken as the systematic error associated with the efficiency correction.

To estimate the contribution associated with event selection criteria, we vary each selection criterion over a suitable range and remeasure \(R_{\text{WS}}\) for each variation. The identification likelihood ratio \(L_K\) is varied over the range 0.5–0.9 for kaon candidates and 0.1–0.5 for pion candidates. The momentum requirement for \(D^*\) candidates is varied over the range 2.3–2.7 GeV/\(c\). For each selection criterion, the largest positive and negative deviation of \(R_{\text{WS}}\) from the nominal value is taken as the systematic error. The error due to multiple candidates is obtained by removing all events containing multiple candidates (8.6% of events) and refitting for \(R_{\text{WS}}\); the deviation observed is taken as the error. To determine the uncertainty associated with background PDF shapes (which are taken from MC and differ for RS and WS events), we vary the parameters of each background PDF by \(\pm 1\sigma\), where \(\sigma\) corresponds to the statistical error from the fit to MC. For each variation, the data is refit and the deviation of \(R_{\text{WS}}\) from the nominal value is recorded. The uncertainty due to a given background PDF is taken as the sum in quadrature of all deviations observed when
varying the individual parameters. The systematic error due to uncertainty in the signal PDF is negligibly small. To check for possible bias in our fit results, we repeat the fit for Monte Carlo samples (each corresponding to the size of the data set) having different values of $R_{ws}$. Comparing the fit results for $R_{ws}$ with the true values shows no visible fit bias. The total systematic error is taken to be the sum in quadrature of all individual contributions. Our final result is

$$R_{ws} = (0.324 \pm 0.008 \pm 0.007)\%.$$  \hspace{1cm} (5)

Multiplying this value by the well-measured RS branching fraction $B(D^0 \rightarrow K^-\pi^+\pi^+\pi^-) = (8.07^{+0.21}_{-0.19})\%$ \cite{21} gives a WS branching fraction

$$B(D^0 \rightarrow K^+\pi^-\pi^+\pi^-) = (2.61 \pm 0.06^{+0.09}_{-0.08}) \times 10^{-4}.$$  \hspace{1cm} (6)

By combining our measurement of $R_{ws}$ with world average values \cite{19} for $x$ and $y$, and recent measurements \cite{20} of $\alpha$ and $\delta$, we extract $R_D$ from Eq. 11. We use a MC method to propagate the errors for the parameters and obtain $R_D = (0.327^{+0.019}_{-0.016})\%$.

TABLE I: Summary of systematic errors for $R_{ws}$. The total systematic error is obtained by summing all contributions in quadrature.

| Source            | $+\Delta R$ (%) | $-\Delta R$ (%) |
|-------------------|-----------------|-----------------|
| Kaon ID           | 0.0008          | 0.0006          |
| Pion ID           | 0.0003          | 0.0024          |
| $D^*$ Momentum    | 0.0029          | 0.0037          |
| Multiple Candidates | 0.0024        | 0.0024          |
| $uds$             | 0.0012          | 0.0002          |

| Sum               | 0.0069          | 0.0070          |

In summary, we have measured the wrong-sign ratio $R_{ws} = \Gamma(D^0 \rightarrow K^+\pi^-\pi^+\pi^-)/\Gamma(D^0 \rightarrow K^-\pi^+\pi^+\pi^-)$ using $e^+e^-$ data collected at or near the $\Upsilon(4S)$ resonance. After correcting for differences in reconstruction efficiencies between RS and WS
events, we obtain $R_{ws} = (0.324 \pm 0.008 \pm 0.007)\%$, where the first uncertainty is statistical and the second is systematic. This is the most precise measurement of $R_{ws}$ to date. Using a MC method to extract $R_{D}$ from Eq. 1, we obtain $R_{D} = (0.327^{+0.019}_{-0.016})\%$. Multiplying $R_{ws}$ by the branching fraction for $D^0 \rightarrow K^- \pi^+ \pi^+ \pi^-$ gives $\mathcal{B}(D^0 \rightarrow K^+ \pi^- \pi^+ \pi^-) = (2.61 \pm 0.06^{+0.09}_{-0.08}) \times 10^{-4}$. This result is substantially more precise than the current PDG value of $(2.61^{+0.21}_{-0.19}) \times 10^{-4}$ [21].

We thank the KEKB group for the excellent operation of the accelerator; the KEK cryogenics group for the efficient operation of the solenoid; and the KEK computer group, the National Institute of Informatics, and the PNNL/EMSL computing group for valuable computing and SINET4 network support. We acknowledge support from the Ministry of Education, Culture, Sports, Science, and Technology (MEXT) of Japan, the Japan Society for the Promotion of Science (JSPS), and the Tau-Lepton Physics Research Center of Nagoya University; the Australian Research Council and the Australian Department of Industry, Innovation, Science and Research; Austrian Science Fund under Grant No. P 22742-N16; the National Natural Science Foundation of China under contract No. 10575109, 10775142, 10875115 and 10825524; the Ministry of Education, Youth and Sports of the Czech Republic under contract No. MSM0021620859; the Carl Zeiss Foundation, the Deutsche Forschungsgemeinschaft and the VolkswagenStiftung; the Department of Science and Technology of India; the Istituto Nazionale di Fisica Nucleare of Italy; The BK21 and WCU program of the Ministry Education Science and Technology, National Research Foundation of Korea Grant No. 2010-0021174, 2011-0029457, 2012-0008143, 2012R1A1A2008330, BRL program under NRF Grant No. KRF-2011-0020333, and GSDC of the Korea Institute of Science and Technology Information; the Polish Ministry of Science and Higher Education and the National Science Center; the Ministry of Education and Science of the Russian Federation and the Russian Federal Agency for Atomic Energy; the Slovenian Research Agency; the Basque Foundation for Science (IKERBASQUE) and the UPV/EHU under program UFI 11/55; the Swiss National Science Foundation; the National Science Council and the Ministry of Education of Taiwan; and the U.S. Department of Energy and the National Science Foundation. This work is supported by a Grant-in-Aid from MEXT for Science Research in a Priority Area (“New Development of Flavor Physics”), and from JSPS for Creative
Scientific Research (“Evolution of Tau-lepton Physics”).
