ABSTRACT

We present new HST optical imagery as well as new UV and IR spectroscopic data obtained with the Hubble Space Telescope and Spitzer Space Telescope, respectively, of the halo planetary nebula DdDm-1. For the first time we present a resolved image of this object, which indicates that the morphology of DdDm-1 can be described as two orthogonal elliptical components in the central part surrounded by an extended halo. The extent of the emission is somewhat larger than was previously reported in the literature. We combine the spectral data with our own previously published optical measurements to derive nebular abundances of He, C, N, O, Ne, Si, S, Cl, Ar, and Fe. The metallicity, as gauged by oxygen, is found to be 0.60 dex below the solar value, confirming DdDm-1’s status as a halo PN. In addition, we find that Si and Fe are markedly underabundant, suggesting their depletion onto dust. The very low C/O ratio suggests that the chemistry of the nebula should be consistent with an oxygen-rich environment. With regard to the unexpectedly low S abundance relative to O often seen in PNe, we find that the sulfur abundance of DdDm-1 is only slightly below the value expected based on the normal lockstep behavior between S and O observed in H II regions and blue compact galaxies. We performed a photoionization model analysis from which we inferred a central star effective temperature and luminosity of 55,000 K and 1000 L☉, respectively, implying an initial progenitor mass of <1 M☉. Finally, we report on a new radial velocity determination from echelle observations.

1. INTRODUCTION

Planetary nebulae (PNe) have long served as useful tracers of galactic interstellar abundances of elements such as O, Ne, S, Cl, and Ar, alpha elements whose abundances are expected to evolve in lockstep due to their common synthesis sites in massive stars. In a recent study of S, Cl, and Ar abundances in over 80 type II PNe located mainly in the northern Galactic hemisphere, Henry et al. (2004) discovered that while Ne and O abundances track each other closely, S abundances in a large fraction of objects fall significantly below the values expected for their O abundances and exhibit a large amount of scatter as well. These authors also showed that the same pattern is present in data in the large southern survey by Kingsburgh & Barlow (1994).

Henry et al. (2004) suggested that this tendency of PNe to display a S deficit, a situation they dubbed the sulfur anomaly, was probably due to the underestimation for many objects of the ionization correction factor used to account for unobserved ions of S when determining the total gas-phase elemental abundance from the optically observable ions of S+3 and S+2. However, measurements of S+3 abundances by Dinerstein et al. (2003) and the results from numerous Infrared Space Observatory (ISO) projects summarized in Pottasch & Bernard-Salas (2006) using the [S iv] 10.5 µm line appear to rule out this explanation, although it is probably too early to draw definite conclusions. Instead, Pottasch & Bernard-Salas (2006) suggested that the sulfur anomaly could result from the depletion of S onto dust due to the formation of sulfides such as MgS and FeS. Sulfide formation is expected to occur most readily in carbon rich environments, i.e., in objects where C/O > 1.

The goal of the project described in this paper is to determine and study the gas phase abundances of the halo PN DdDm-1, an object for which we present new optical imagery as well as spectroscopic measurements of important UV and IR emission lines. DdDm-1 was chosen primarily because of the large amount of data, both new (presented here) and previously published for this object. Of the many catalogued PNe in our Galaxy, only about 12 are believed to be located in the halo. Abundance studies of these objects can be used to determine the chemical composition

1 This work is based in part on observations made with the Spitzer Space Telescope, which is operated by the Jet Propulsion Laboratory, California Institute of Technology under a contract with NASA. Support for this work was provided by NASA through an award issued by JPL/Caltech.

2 Based on observations made with the NASA/ESA Hubble Space Telescope, obtained from the data archive at the Space Telescope Institute. STScI is operated by the association of Universities for Research in Astronomy, Inc., under the NASA contract NAS 5-26555.

of the halo and can provide additional insight into the evolution of this region of the Milky Way. These objects have consistently been shown to possess subsolar levels of metals (Torres-Peimbert et al. 1981; Peña et al. 1992; Howard et al. 1997; Dinerstein et al. 2003). DdDm-1 has been included in many large abundance surveys but has only been studied in detail in a few instances, e.g., Barker & Cudworth (1984), Dinerstein et al. (2003), and Wright et al. 1981; Pen˜a et al. 1992; Howard et al. 1997; Dinerstein et al. 2003). DdDm-1 has been included in many large abundance surveys but has only been studied in detail in a few instances, e.g., Barker & Cudworth (1984), Dinerstein et al. (2003), and Wright et al. (2005). Here we focus on it exclusively.

In this paper we present new optical HST imagery, new UV data taken with the Faint Object Spectrograph (FOS) on Hubble Space Telescope (HST), and new IR data taken with the Infrared Spectrograph (IRS) on the Spitzer Space Telescope. The imagery allows us for the first time to resolve the nebula and study its morphology. Then, combining the spectral data with our own previously published optical data, we compute the abundances of He, C, N, O, Ne, Si, S, Cl, Ar, and Fe. We also use the program CLOUDY (Ferland et al. 1998) to calculate photoionization models of DdDm-1 in order to infer the effective temperature and luminosity of the central star. Since the Spitzer data allow us to determine the abundance of S$^+$, the primary unobservable ion when only optical measurements are available, we evaluate the accuracy of the sulfur ionization correction factor for DdDm-1. With a new sulfur abundance in hand, we then assess the S deficit of DdDm-1, as well as check on the consistency of the deficit’s magnitude with the value of C/O derived from our new UV measurements. Finally, we present new echelle data for DdDm-1 and determine its radial velocity.

The paper is organized as follows. In § 2, we discuss our observations; § 3 contains a description of our procedure for computing abundances; in § 4 we discuss our results, and we give a summary and conclusions in § 5.

2. OBSERVATIONS

2.1. Optical Imaging

In Figure 1 we present what we believe to be the first resolved image of DdDm-1 in the literature, taken from a 1993 WFPC1 image made with the Hubble Space Telescope. (Recently, Wright et al. (2005) obtained an image of DdDm-1 which, according to the authors, was not well resolved.) The nebula was exposed for 40 s through the F675W filter, which covers Hα and nearby emission lines. In our analysis we used the processed WFPC1 image from STScI (W1j00201T), which was corrected for CCD artifacts and noise. Cosmic rays were removed using a combination of a median filter and direct inspection. A 60 × 60 array (6′′ × 6′′) centered on the nebula was extracted for our analysis. Then, the image was rebinned into a 120 × 120 pixel array using a cubic spline interpolation, to give 0.05″ pixels. A theoretical point-spread function was generated using the STScI Tiny Tim software appropriate to the location of the nebula on the WFPC1 filter, and the observation date. This point-spread function (PSF) was also rebinned into 0.05″ pixels as per the nebula image. The STSDAS Lucy software in the restoration package was then used to deconvolve the DdDm-1 image with this PSF. Our results appeared best for about 35 iterations. We then rotated the images 105° counterclockwise to align them with the equatorial coordinate system. The final image is 3″ × 3″, with north up and east to the left. Figure 2 shows the same image as the one in Figure 1 but with contours added. The latter were generated using the disconlab software in IRAF.

From the deconvolved image and contoured overlay in Figure 1 and 2, the structure of DdDm-1 is seen to be elliptical with two central components possibly surrounded by an extended (and nearly circular) halo. Evidence for a central star is also seen in the center of the brighter inner ellipse, which has a major axis of ~0.50″ along a P.A. = 65° and minor axis of ~0.35″. This is surrounded by a fainter outer elliptical nebula with a major axis of ~1.1″ and minor axis ~0.95″ which is extended approximately orthogonal to the major axis of the inner ellipse. These are somewhat larger dimensions for DdDm-1 than previously reported in Ackar et al. (1992). Indeed, a logarithmic stretch of our processed image suggests the halo of DdDm-1 may have a diameter of upward of ~1.75″ (but difficult to define due to the HST spherical aberration scattered light problems at that time).
2.2. Spectrophotometry

Here we report spectroscopically observed emission line fluxes in the UV, optical, and IR spectral regions. The previously unpublished UV observations were obtained with the FOS on HST, while the optical data were measured with the Goldcam on the 2.1 m telescope at Kitt Peak National Observatory (KPNO) and reported by Kwitter & Henry (1998). We also present new IR measurements obtained with the Spitzer Space Telescope with the IRS.

Finally, we report on radial velocity measurements obtained with the echelle spectrograph on the 4 m telescope at KPNO. These sets of observations are described separately in detail below.

Our complete list of emission line measurements is presented in Table 1, where the first column lists the line wavelength and identification, the second column contains the relevant line strength, with the values predicted for DdDm-1's temperature and density by the models presented in Table 1 and discussed in § 3.1. Because the angular size of DdDm-1 is smaller than the size of all slits employed in the observations, we are confident that the entire flux was observed in each line within each spectral range. Thus, no adjustments were necessary in order to place all line strengths on the same scale. In the following subsections we individually describe the observations obtained within the three spectral regions. Finally, in performing the dereddening calculations we used the reddening functions of Seaton (1979) for the UV, Savage & Mathis (1979) for the optical, and Indebetouw et al. (2005) and Rieke & Lebofsky (1985) shortward and longward of 8 μm in the IR, respectively.

2.2.1. Ultraviolet Data

DdDm-1 was observed with the FOS on the HST during 1995 October 5 as part of the Cycle 5 program GO6031. Five “H-series” gratings were used, covering the spectral range 1087–6817 Å. The observations were made through the 0.9" circular aperture (post-COSTAR) with a peak-up centering the central star in the aperture. Figure 3 shows the UV spectrum from 1700 to 3250 Å, obtained by splicing together the archival spectra taken with the G190H (1140 s), and G270H (480 s) gratings. Not shown is the G130H (2270 s) spectrum, which exhibits only a strong continuum and no obvious emission lines. Cospatial optical wavelength spectra were also obtained with the G400H (90 s) and G570H (60 s) gratings, which permitted scaling of the UV lines to the H I Balmer lines, enabling an accurate tie-in between the UV spectra and the ground-based optical and Spitzer IR spectra in this study. All of the FOS spectra that were analyzed have been recalibrated by the POA-CALFOS pipeline developed by the ST-ECF in 2002 (Alexov et al. 2002).

The strongest emission lines in the far-UV are dielectronic recombination pairs of O III λ1663, and Si iii λ1882, 1892 Å (resolved and unusually strong relative to C iii)). In the mid-UV, the dominant emission lines are the C ii λ1335, 1337 multiplet, [O ii] λ1171, 1173 Å, [O i] λ7774, 7775, 7780 Å, and Mg ii λλ2795, 2803 Å. Table 1 gives the measured strengths of the important UV abundance diagnostic lines measured from these spectra. Fluxes of the UV lines were measured from Gaussian fits to their profiles. We further note that the errors in the UV line strengths are purely statistical (the square root of their FWHM times the rms fluctuations of the nearby continuum) and do not include possible errors in the FOS calibrations or extinction.

2.2.2. Ground-based Optical Data

The optical data were obtained at KPNO in 1996 May, using the 2.1 m telescope and Goldcam CCD spectrograph. The spectral range from 3700 to 9600 Å was covered in two parts, with overlap from 5700 to 6800 Å. The total blue integration time was 600 s and the red was 2400 s. The data were reduced with standard IRAF routines. Further details of the observations and reductions can be found in Kwitter & Henry (1998). The merged spectrum from KPNO is shown in Figure 4. We point out that our measurement of the flux in Hβ agrees closely with the value reported by Dinerstein et al. (2003).

2.2.3. Infrared Data

DdDm-1 was observed with IRS (Houck et al. 2004) on the Spitzer Space Telescope in 2006 June. We used the Short Low (SL1 and SL2), Short-High (SH), and Long-High (LH) modules, giving coverage from 5.2 to 37.2 μm. Details of the observations are given in Table 2.

Spectra were extracted using SPICE, a Java tool available from the Spitzer Science Center Web site. Since DdDm-1 has an angular diameter of 0.6″ (Acker et al. 1992), i.e., smaller than the spatial resolution of all the IRS modules, it was extracted as a point source, and we presume that we have detected all of the nebular flux. This is confirmed by the measured fluxes relative to H β of the strongest observed H transitions (9–7 at 11.3 μm and 7–6 at 12.4 μm), which agree, within the measurement uncertainties, with the values predicted for DdDm-1’s temperature and density by the models presented in Table 1 and discussed in § 3.

Orders were trimmed and merged and line fluxes for DdDm-1 were measured with SMART (Higdon et al. 2004), which produces fluxes and uncertainty estimates for each line from its line-fitting routine. SMART was also able to fit a thermal continuum to the SH-LH spectrum, obtaining a temperature of 125 K, typical of thermal dust emission. Figures 5 and 6 show the IRS spectra.

2.3. Echelle Data and the Radial Velocity of DdDm-1

DdDm-1 was observed in 2002 June using the echelle spectrograph on the Mayall 4 m telescope at Kitt Peak. We used the T2KB 2048×2048 pixel CCD, binned 2×2. We observed in two configurations in order to cover the full spectral range: the blue configuration, which spans wavelengths between approximately 4300 and 7200 Å, and the red configuration, with a spectral range between 6500 and 9600 Å. Total exposure time was 6600 s. We used the 79″–63″ echelle grating and the 226–2 cross disperser on all nights. The reductions were done using the echelle package in IRAF. Although accurate flux calibration among the observed echelle orders proved impossible, we were able to extract kinematic information from the observations.

Observed and measured wavelengths for a selection of lines in the spectrum are given in Table 3; based on these measurements we find the radial velocity of DdDm-1 to be −300.9 ± 1.4 km s⁻¹. We used the rvcorrect task in the astutil package in IRAF to correct for the Earth’s rotation and orbital motion at the time of the observations and found a correction of −9.4 km s⁻¹, giving a heliocentric radial velocity of −310.3 ± 1.4 km s⁻¹. The radial velocity of DdDm-1 has been measured by Barker & Cudworth (1984) to be −304 ± 20 km s⁻¹, and by Wright et al. (2005) as −317 ± 13 km s⁻¹; our value agrees very well with both of these, and is better constrained.

*a* Deblended.  
*b* Measured in ergs cm$^{-2}$ s$^{-1}$ in our extracted spectra.  
$^c$ A distance of 11.4 kpc from Cahn et al. (1992) was used to obtain this value from the H/$\beta$ luminosity predicted by the model.

We take the opportunity here to mention that the echelle spectrum contains many forbidden iron lines that are split. We will address the issue of DdDm-1’s expansion and ramifications for its morphology in a future paper.

3. ANALYSIS

We performed both an empirical and a numerical analysis of DdDm-1, using the line strengths reported in the previous section and listed in Table 1. We first employed the abundance software package ELSA (M. Johnson et al. 2007, in preparation), a new C program based on a five-level atom routine, to derive empirical electron temperatures and densities as well as ionic and elemental abundances of numerous elements. We then performed detailed photoionization model calculations of DdDm-1 using the program Cloudy (Ferland et al. 1998), version 07.02.0.0. The purpose of this numerical work was to extract information about the central star. We now describe each of the steps in detail.

3.1. Empirical Analysis

In this step, strengths of many of the emission lines in Table 1 were entered as input in ELSA (M. Johnson et al. 2007, in preparation), a multilevel atom program descended from the much used and tested program ABUN by R. B. C. Henry (Kwitter & Henry 2001). The program then derived electron temperature and density estimates based on temperature-sensitive or density-sensitive line sets and then calculated ionic abundances. Finally, total elemental abundances were determined through the use of ionization correction factors which account for the contributions of unobserved ions to the total. Results for electron temperatures and densities, ionic abundances, and elemental abundances derived...

using the empirical method are presented in Tables 4, 5, and 6, respectively. Table 6 is discussed in detail in § 4.1.

In Table 4 we report the values of five electron temperatures from diagnostic emission line ratios of [O ii], [N ii], [O i], [S ii], and [S iii], and three values of electron density, [S ii], [Cl iii], and [S i]. (The emission lines used to calculate these values are provided in a footnote to the table.) Note that for the [S ii] temperature the 9532 line strength was used, since the 9532 line only, since the 9532 line was misreported in Henry et al. (2004). This temperature was based on the 9069 line only, since the 9069 line exceeded the theoretical value, indicating that 9069 Å is partially absorbed by the Earth’s atmosphere.

For comparison purposes we have included results from Clegg et al. (1987) and Barker & Cudworth (1984) for ions and emission lines provided in those two studies. (An additional comparison in the cases of Ne and S will be made with the results of Dinerstein et al. [2003] below.) For the major ions there appear to be no significant discrepancies among the three studies. The situation is nearly the same for the ICFs, although the moderate variance among derived values for N suggests that the abundance of this major element may be in dispute.

3.2. Numerical Analysis

We next employed the program Cloudy (Ferland et al. 1998), version 07.02.01, to calculate detailed photoionization models of DdDm-1 with the goal of extracting some additional information about the central star of DdDm-1, such as its effective temperature and luminosity. Cloudy uses a trial set of input parameters whose values are estimated by the investigator, and predicts emission line strengths and physical conditions for the nebula. In calculating the models, our empirically derived abundances in column (2) of Table 6 and electron density from Table 4 were used to set the input parameter values in the first model. The predicted emission line strengths of that model were then compared with their observed counterparts, the parameter values were adjusted accordingly, and a new model was calculated. This process was repeated until a suitable match between theory and observation was obtained. Note that the images of DdDm-1 presented above support our use of a relatively simple density distribution for our modeling exercise, since they suggest a smooth distribution of matter and a symmetrical shape. We present the results for two models, 18 and 32, in columns (5) and (6) of Table 1.

For model 18 the input central star flux was taken from the H-Ni grid of synthetic central star fluxes by Rauch (2002), which was calculated by assuming non-LTE hydrostatic conditions, line blanketing, and plane-parallel geometry. The luminosity of the central star was taken to be 1000 Lsun. The model was radiation bounded with a constant total density of 4000 cm^-3 throughout the nebula, consistent with the smooth appearance of the nebula in Figures 1 and 2 and the electron density reported in Table 4; the filling factor was unity. Model 18 was successful in reproducing most of the important lines (shown in bold) in Table 1.

### Table 4

| Parametera | This Paper | C87b | BC84c | HBK04 | WLBO5d |
|------------|-----------|-----|------|-------|--------|
| T_{[O ii]} | 12060(±690) | 11800(±800) | 12100(±600) | 11700 | 12300 |
| T_{[N ii]} | 12940(±1236) | 11000(±1200) | 12800(±1000) | 11400 | 12980 |
| T_{[S ii]} | 15830(±9500) | ... | 110000(±2000) | 10100 | 16110 |
| T_{[S iii]} | 15650(±13760) | ... | 180000(±6000) | 7900 | 13850 |
| T_{[N iii]} | 12950(±1392) | ... | 115000(±3000) | 12700 | ... |
| N_{[Cl ii]} | 4092(±2491) | 4400 | 32000(±1300) | 4000 | ... |
| N_{[S ii]} | 3973(±4427) | ... | ... | ... | ... |
| N_{[S iii]} | 3293(±743) | ... | ... | ... | ... |

a Wavelengths (in angstroms, unless noted otherwise) of emission lines used to calculate electron temperatures and densities were: T([O ii]): 5007, 4363; T([N ii]): 6584, 5755; T([O i]): 3727, 7324; T([S ii]): 6716, 6731, 4071; T([S iii]): 9532, 9069, 6312; N_{[S ii]}: 6716, 6731; N_{[S iii]}: 5518, 5538; N_{[Cl ii]}: 18.7μm, 33.5μm. Temperatures and densities are expressed in kelvins and cm^-3, respectively.

b Clegg et al. (1987).

c Barker & Cudworth (1984).

d Wesson et al. (2005).

e We note that the value of 7900 K for T_{[S ii]} was misreported in Henry et al. (2004).

f This temperature was based on the 9069 Å line only, since the 9069 Å line exceeded the theoretical value, indicating that 9069 Å is partially absorbed by the Earth’s atmosphere.

$^c$ Value included in weighted mean (wm), weighted by observed flux.
$^d$ Not included in total oxygen abundance calculation.
$^e$ Clegg et al. (1987) included the O$^+$, O$^+$, and O$^+$2 abundances and assumed an ICF of unity.
$^f$ Abundance derived from C ii 4267.
$^g$ Based on Ar$^+$2 only.
However, the predicted strength of [O iii] 4363 was somewhat higher than the observed value, while the [S ii] λλ6716, 6731 line strengths were also overpredicted by the model. Numerous models were run in an effort to reduce these particular problems, but improvements in these lines came only with serious damage to other predicted line strengths; in the case of sulfur this often meant poor matches with the [S iii] and [S iv] lines. An example is our attempt to reduce [S ii] emission by truncating the nebula, i.e., making it matter bounded with the intention of reducing the volume of gas in the outer region of the nebula where large amounts of [S ii] are produced. However, this led to a significant reduction of emission from ions such as [O ii] and [N ii], making the altered model an untenable solution.

Model 32 differs from 18 most significantly in the character of the central star. For this model we used a blackbody spectrum of $T_{\text{eff}} = 40,000$ K with a bolometric luminosity of $10^5 L_{\odot}$. The other major difference was that model 32 had a filling factor of 0.5. Otherwise the density was unchanged and the abundances were very similar to those employed in model 18. For this model, the prediction of [O iii] 4363 is slightly better, although this time it is below rather than above the observed value. In addition, the predicted strengths of [O iii] 5507 is below the observed level. Model 32 was primarily an attempt to achieve improved agreement in the [S ii] lines over that found in model 18. However, in doing so the level of agreement in the near IR lines of [S iii] and [S iv] at 10.5 μm became worse.

The main parameters for models 18 and 32 are summarized in Table 7. We prefer model 18, since it includes the use of a realistic central star model spectrum, and its predicted line strengths satisfactorily match most of the important observed line strengths, with the exceptions noted above. In addition, this model’s H β luminosity closely matches the observed value. In the case of model 18 we point out that the model abundances in Table 7 which produced the generally good agreement between observed and predicted line strengths in Table 1 are very consistent with our empirically derived abundances in Table 6.

4. DISCUSSION

4.1. Adopted Abundances of DdM-1

Our final abundance results for DdM-1 are presented in column (2) of Table 6. Note that our value for S was derived by including the abundance of S$^{3+}$ inferred from [S iv] 10.5 μm, along with S$^+$ and S$^{2+}$. The uncertainties given in column (2) are statistical and based on error propagation results calculated by ELSA from estimated line strength errors. Columns (3)–(7) of Table 6 show values for comparison purposes from Clegg et al. (1987), Barker & Cudworth (1984), and Wesson et al. (2005) for DdM-1, Asplund et al. (2005) for the Sun, and Esteban et al.
TABLE 8

| Parameter                  | Dinerstein et al. | This Paper |
|----------------------------|-------------------|------------|
| S/H                        | 2.2 $\times$ 10^{-7} | 1.5 $\times$ 10^{-7} |
| S^{2+}/H                   | 1.63 $\times$ 10^{-6} | 1.66 $\times$ 10^{-6} |
| S^{3+}/H                   | 2.3 $\times$ 10^{-7} | 2.1 $\times$ 10^{-7} |
| Total S/H                  | 2.1 $\times$ 10^{-6} | 2.1 $\times$ 10^{-6} |
| Ne^{2+}/H                  | 2.1 $\times$ 10^{-6} | 8.46 $\times$ 10^{-6} |
| Ne^{3+}/H                  | 1.17 $\times$ 10^{-5} | 1.6 $\times$ 10^{-5} |
| Total Ne/H                 | 1.4 $\times$ 10^{-5} | 2.1 $\times$ 10^{-5} |

The abundances in the figure are taken, all normalized to solar values from Asplund et al. (2005). For clarity, uncertainties are not plotted; they generally have values of 0.10 dex or less.

(1998) for the Orion Nebula, respectively. The last column provides a comparison of our abundances in column (2) with solar abundances, using the usual bracket notation defined in the table footnote. Note that since neither Si nor Fe is currently included in ELSA, our final values for these elements correspond to the model input values for model 18.

There is good agreement among the four studies of DdDm-1 represented in Table 6 for He/H, O/H, Ne/H, Si/H, and S/H, where all ratios but the first one represent alpha elements, and therefore their abundances are expected to exhibit lockstep behavior. In addition, our value for Fe/H agrees reasonably well with that published by Clegg et al. (1987).

Our N/H abundance agrees closely with those found in the other two studies. Our C/H measurement is also in line with the results of Clegg et al. (1987) and Wesson et al. (2005), although the C/H value provided by Barker & Cudworth (1984) is nearly 2 orders of magnitude above the other three. We note that Barker & Cudworth (1984) determined their C abundance using the recombination line C II 4267, and it is often the case that abundances derived from recombination lines yield significantly higher values than abundances determined from collisionally excited lines (Wesson et al. 2005). Unlike Barker & Cudworth, we did not detect 4267 in our spectrum, nor apparently did Wesson et al. (2005). However, an upper limit for the 4267 line strength in our spectrum is 0.03 (Hβ = 100) or about 1/10 the strength reported by Barker & Cudworth (1984). The correction for reddening is insignificant. Running this value through ELSA produces an upper limit on the abundance ratio of C^{2+}/H of 3.1 $\times$ 10^{-5}, or about 1/10 the level of this ratio determined by Barker & Cudworth (1984). In terms of C/O, our result and that of Clegg et al. (1987) and Wesson et al. (2005) suggest that DdDm-1 is a C-poor (or O-rich) system (C/O < 1), while Barker & Cudworth’s (1984) value implies a C-rich (O-poor) system (C/O > 1).

Dinerstein et al. (2003) used infrared and optical line measurements acquired at the IRTF and the 2.7 m telescope at McDonald Observatory, respectively, to study abundances of S and Ne in DdDm-1. Table 8 provides a comparison of their results with ours. The agreement between the two groups is remarkably good, all normalized to solar of a ratio on the horizontal axis. [See the electronic edition of the Journal for a color version of this figure.]

As alpha elements, S and O are expected to evolve in lockstep, as we explained above. Henry et al. (2004) found that while this

$^7$ Since alpha elements result from He burning processes, one expects them to track each other, and therefore the offsets should be roughly the same for any one object.
is true when $\text{H} \alpha$ regions and blue compact galaxies are used to probe the abundances of these two elements, the expectation is often unmet in the case of PNe.\(^8\) These authors found marked scatter in S abundances for PNe of roughly the same O abundance. In addition, S abundances were regularly determined to be below the expected level for a given O abundance by 0.3 dex on average. This unexpected finding was referred to as the sulfur anomaly by Henry et al. (2004). In the specific case of DdDm-1, however, Henry et al. (2004) found that its S abundance was close to the value expected from its O abundance.

We now revisit this situation with our updated S and O abundances obtained here. Employing our O abundance in Table 6 along with a least-squares fit to measurements of $12 + \log (\text{S/H})$ versus $12 + \log (\text{O/H})$ in $\text{H} \alpha$ regions in M101 (Kennicutt et al. 2003) and blue compact galaxies (Izotov & Thuan 1999) to estimate the expected S abundance,\(^9\) we obtain $12 + \log (\text{S/H}) = 6.47$ as the expected value for S. Our corresponding measured value is 6.31, yielding a sulfur deficit of $6.47 - 6.31 = 0.16$, which is close to the uncertainty in the S abundance and less than the typical value of 0.3 for the sulfur deficit found by Henry et al. (2004). We conclude that the S and O abundances associated with DdDm-1 are consistent with the expected lockstep behavior for these two elements.

It has been suggested by Pottasch & Bernard-Salas (2006) that the sulfur anomaly found by Henry et al. (2004) could be the result of dust formation. In particular, S may be removed by the formation of compounds such as MgS and FeS in those PNe exhibiting large S deficits. In fact, this would be expected to occur more readily in C-rich environments, where sulfide formation is favored. Interestingly, the low C abundance which we find for DdDm-1, with C/O $< 1$, implies that oxygen-rich chemistry exists in the nebula of DdDm-1 and that dust composition should be dominated by silicates and other oxygen-rich species and not sulfides. Thus, if the sulfur anomaly is indeed related to sulfide formation, then the small S deficit that we observe in DdDm-1 would be expected as the result of its low value for C/O.

Further evidence for the low C/O ratio in DdDm-1 is the absence of polycyclic aromatic hydrocarbon (PAH) emission bands in the IRS SL spectra (Fig. 5). The IDL routine pahfit (Smith et al. 2007) was applied to the SL spectra, and no evidence was found of the PAH emission features near 3.3, 6.2, 7.7, 8.7, and 11.3 $\mu$m, which are strong in the IR spectra of many PNe (Cohen & Barlow 2005). In their study of ISO spectra of 43 PNe, Cohen & Barlow found that 17 objects exhibited strong PAH emission and that the 7.7 and 11.3 $\mu$m PAH band strengths relative to the total infrared luminosity are correlated with the nebular C/O ratio. As is evident from our IRS spectra in Figures 5 and 6, all of the emission features seen in DdDm-1 are nebular lines with no broad PAH emission evident. However, a strong IR continuum, apparently due to warm dust emission, is evident. Blackbody fits to the LH spectrum using SMART give a good fit for a temperature of $125 \pm 7$ K. This is comparable to other PNe studied by ISO and Spitzer. Finally, no significant silicate absorption bands at 9.7 and 18 $\mu$m are visible in the IRS spectra. These findings further support our result for a low C/O ratio in DdDm-1, as well as the likelihood that Si/O is low as well.

4.2. Central Star Properties

The central star temperature which we infer for DdDm-1 is $55,000 \, \text{K}$ with a luminosity of $10^3 L_\odot$, based on our preferred model 18 (see Table 7). Recall that model 18 employed a stellar spectrum from Rauch (2002) which was calculated by assuming realistic conditions of high gravity and low metallicity for the central star. Our effective temperature is somewhat higher than the value of 40,000 ($\pm 5000$) K determined by Peña et al. (1992) and 45,600 K estimated from models by Howard et al. (1997). This situation may reflect our use of model stellar fluxes calculated specifically for a low-metallicity regime.

These derived central star properties along with the O abundance for DdDm-1 can be compared with AGB star model tracks calculated by Vassiliadis & Wood (1994) in order to infer a progenitor mass. Data in their Figure 7 suggests that the central star of DdDm-1 is a He-burning object which had a main-sequence mass of $<1 M_\odot$. This relatively low mass is consistent with the idea that DdDm-1 is associated with an old stellar population such as that found in the halo.

5. SUMMARY AND CONCLUSIONS

We have reported on new IR and UV spectra of the halo planetary nebula DdDm-1 obtained with the Spitzer Space Telescope with the IRS and Hubble Space Telescope with the FOS, respectively. By combining these new data with existing optical measurements, the nebular abundances of He, C, N, O, Ne, Si, S, Cl, Ar, and Fe were determined. The abundance analysis included the computation of detailed photoionization models which made use of an input stellar atmosphere whose characteristics were consistent with a central star of low metallicity. We also present new echelle data for DdDm-1. We have found the following:

1. We present what we believe to be the first resolved image of DdDm-1. Reconstructed imagery taken with the HST in 1993 indicated that the morphology of DdDm-1 can be described as two orthogonal elliptical components in the central part surrounded by an extended halo. The extent of the emission is somewhat larger than was previously reported in the literature.

2. We present new UV, IR, and echelle data, where the first two sets were acquired using HST and Spitzer, respectively.

3. Our new determinations of the Si and Fe abundances indicate that their levels are far below those expected from the metallicity of DdDm-1, possibly indicating that their gas-phase abundances have been depleted by dust formation.

4. We determine that C/O $< 1$. A C/O ratio below unity suggests that the chemistry of the nebula is O-rich in character. Thus, sulfides should be absent in any dust that has formed in the environment of DdDm-1.

5. We find that the abundance of S$^{+3}$ which we determined directly from our new [S iv] 10.5 $\mu$m measurement agrees closely with another modern one by Dinerstein et al. (2003) and is consistent with the level predicted by the value of the ICF obtained when only optical lines of [S ii] and [S iii] are used. The small abundance of S$^{+3}$ that we derive indicates that DdDm-1 is a relatively low-excitation nebula when compared with other PNe.

6. Our total gas-phase S abundance for DdDm-1 is consistent with the value expected from its O abundance, under the assumption of lockstep behavior between these two elements. Thus DdDm-1 has a negligible S deficit. On the other hand, if the large S deficits observed in other PNe are indeed due to sulfide formation in a C-rich environment as others have suggested, then the small S deficit of DdDm-1 is entirely consistent with its C-poor properties.

7. For the central star we find that $T_{\text{eff}} = 55,000 \, \text{K}$ and $L = 1000 L_\odot$. Comparing the star with theoretical model tracks suggests that it is a He-burning object with a mass of less than $1 M_\odot$.

8. The heliocentric radial velocity of DdDm-1 is $-310.3 \pm 1.4 \, \text{km s}^{-1}$.

\(^8\) See also the discussion of Ne and S abundances in H $\alpha$ regions in Lebouteiller et al. (2008).

\(^9\) $12 + \log (\text{S/H}) = 0.888(12 + \log (\text{O/H})) - 0.683$. 
All four authors thank their respective institutions for travel support for attending IAU Symposium 234 on planetary nebulae in spring 2006, where we had the opportunity to meet and discuss various problems surrounding this and related studies of target objects. R. J. D. and K. B. K. wish to thank Rice graduate student Greg Brunner for applying PAHFIT and SMART blackbody analyses to our Spitzer IRS spectra. R. B. C. H. acknowledges fruitful discussions with Angela Speck about dust formation in PNe. K. B. K. thanks R. Gruendl and Y.-H. Chu for considerable advice and assistance with the echelle observations. R. B. C. H. is also grateful for partial support of his research by NSF grant AST 03-07118 to the University of Oklahoma. Finally, we thank an anonymous referee for making suggestions which improved the paper.
