Abstract

Background: Ichthyosaurs are reptiles that inhabited the marine realm during most of the Mesozoic. Their Cretaceous representatives have traditionally been considered as the last survivors of a group declining since the Jurassic. Recently, however, an unexpected diversity has been described in Upper Jurassic–Lower Cretaceous deposits, but is widely spread across time and space, giving small clues on the adaptive potential and ecosystem control of the last ichthyosaurs. The famous but little studied English Gault Formation and ‘greensands’ deposits (the Upper Greensand Formation and the Cambridge Greensand Member of the Lower Chalk Formation) offer an unprecedented opportunity to investigate this topic, containing thousands of ichthyosaur remains spanning the Early–Late Cretaceous boundary.

Methodology/Principal Findings: To assess the diversity of the ichthyosaur assemblage from these sedimentary bodies, we recognized morphotypes within each type of bones. We grouped these morphotypes together, when possible, by using articulated specimens from the same formations and from new localities in the Vocontian Basin (France); a revised taxonomic scheme is proposed. We recognize the following taxa in the ‘greensands’: the platypterygines ‘Platypterygius’ sp. and Sisteronia seeleyi gen. et sp. nov., indeterminate ophthalmosaurines and the rare incertae sedis Cetarthrosaurus walkeri. The taxonomic diversity of late Albian ichthyosaurs now matches that of older, well-known intervals such as the Toarcian or the Tithonian. Contrasting tooth shapes and wear patterns suggest that these ichthyosaurs colonized three distinct feeding guilds, despite the presence of numerous plesiosaur taxa.

Conclusion/Significance: Western Europe was a diversity hot-spot for ichthyosaurs a few million years prior to their final extinction. By contrast, the low diversity in Australia and U.S.A. suggests strong geographical disparities in the diversity pattern of Albian–early Cenomanian ichthyosaurs. This provides a whole new context to investigate the extinction of these successful marine reptiles, at the end of the Cenomanian.

Introduction

Ichthyosauria was a successful clade of marine sauropsids that spanned most of the Mesozoic, from the Olenekian (Early Triassic) to the end of the Cenomanian (Late Cretaceous). When compared to the Triassic and the Jurassic, the Cretaceous record of ichthyosaurs is generally poor [1]. As a result, only minimal attention has been drawn to the Cretaceous representatives of Ichthyosauria in the past. The last in-depth taxonomic reviews of Cretaceous ichthyosaurs are those of McGowan [2], focusing on North American material, and Bardet [3], mainly reviewing Late Cretaceous ichthyosaur occurrences. McGowan [2] merged all valid species within a single genus, Platypterygius. Cretaceous ichthyosaurs were then considered as undiversified, despite their worldwide distribution (e.g. [4]). Their extinction, at the Cenomanian–Turonian boundary [3], was therefore considered as inconsequential because the group was already on the decline since the Jurassic [5]. This vision of ichthyosaur evolution has been substantiated by recent reassessments of the abundant Australian and American material, which regarded both these assemblages as monospecific: ‘Platypterygius australis’ in Australia [6–13] and ‘Platypterygius americanaus’ in U.S.A. [14]. Yet, numerous new forms have recently been described in Canada and western Eurasia, profoundly modifying the traditional view of ichthyosaur’s protracted decline in the Cretaceous [1,15–23].

However, these recent findings are widely spread across time (Berriasian–Albian, around 46 Myr) and space (Canada, Argentina, England, Germany, and Russia), and evidence of co-occurring taxa is extremely scarce. Indeed, only three Cretaceous formations have yielded more than one ichthyosaur taxon: the Wabiskaw Member of the Clearwater Formation (early Albian of Canada; two taxa [22,23]), the Loon River Formation (middle Albian of Canada; two taxa [15,16]), and an unnamed formation from the Barremian of Russia (likely two taxa [21]). Therefore, although recent data indicates ichthyosaurs were not a ‘dying group’ as previously supposed, this new data gives little clues on...
the ecological diversity and ecosystem control of the Cretaceous ichthyosaurs: were Cretaceous ichthyosaurs a frequent but minor component of marine trophic webs or did they occupy several ecological niches within marine ecosystems as they did in the past (e.g. Early Jurassic Europe [24,25])? Answering this question requires geological formations containing numerous marine tetrapods – a rare resource in the Early Cretaceous strata – but does not necessarily require articulated specimens.

Here, we analyze the diversity of Albian–basal Cenomanian ichthyosaur assemblages of western Europe, by focusing on the Albian Gault Formation (UK), the Albian–Cenomanian Upper Greensand Formation (UK), the basal Cenomanian Cambridge Greensand Member (base of the Lower Chalk Formation, UK), and the Albian part of the Marnes Bleues Formation (France). The abundant material (several thousands specimens in total) from these localities provides precious data on the taxonomic and ecological diversity of some of the last representatives of Ichthyosauria. In order to evaluate this diversity, we (1) thoroughly reassess the taxonomy of the ichthyosaur assemblages from these formations and (2) evaluate the ecological diversity of these taxa by analyzing their tooth shape, tooth wear, and their relative abundances. Then, these western European assemblages are discussed within the worldwide context of ichthyosaur diversity during the Cretaceous by (3) plotting taxonomic richness curves and (4) evaluating geographical disparity of diversity, providing a background for future analyses of their final extinction.

Assessment of the taxonomic diversity in bone-bed like deposits

**Taxonomic diversity.** Two bone-bed-like deposits have been investigated during this research: the Upper Greensand Formation and the Cambridge Greensand Member. Their faunal diversity must be cautiously assessed, because most of the material is disarticulated. In the sections below, we detail the methodology used to evaluate the taxonomic diversity of these remains and the relative abundances of each recognized taxon.

More than one thousand ichthyosaur specimens (without counting the isolated teeth) are held in the Cambridge Greensand Member collections of the CAMSM, IRSNB, GLAHM, LEICT, and NHMUK. Most of them are disarticulated and consist of isolated bones that were either purchased by or donated to these institutions. We accessed and analyzed all these collections; we used a simple, three-step process to assess the taxonomic diversity of these remains. First, we established morphotypes within each series of abundant and usually diagnostic bones (skull roof bones, teeth, humeri, and femora; see Table 1 for a list of the morphotype recognized and Text S5 for a determination key); however, all specimens and all kinds of fragments, including rostra, centra, ribs, gastralia, phalanges, etc. have been investigated. Then, we used articulated specimens from the upper (unreworked) part of the Cambridge Greensand Member and from coeval deposits of the Voucontian Basin (France) to group some of these morphotypes together. Finally, we compared these morphotypes or groups of morphotypes to known taxa in the literature in order to 'translate' these entities into taxa, when possible. However, we refrained from assessing the diversity at the specific level, especially because of the numerous problems related to the species currently referred to as ‘Platypterygius’ [18]. Moreover, the taxonomic value of the numerous small morphological variations observed in the sample is difficult to assess. Nevertheless, some bones, such as humeri and femora contain more distinct morphotypes than the number of taxa (genera) recognized, suggesting a higher diversity at a lower taxonomic level, probably reflecting the specific level. On the other hand, some of these morphotypes contain only a few specimens, so intraspecific variation should also be considered as a possible explanation for the high number of humeral and femoral morphotypes. Indeed, slight inter-adult and ontogenetic variability of humeral distal facets has been recognized in the platypterygine ophthalmosaurid ‘P. australis’ [26,27].

All the specimens from these deposits cannot be determined, because isolated elements from the rostrum, mandible and axial skeleton are not diagnostic and because of the presence of small, probably juvenile specimens lacking distinguishing features, in addition to damaged specimens. In total, only 124 specimens of the Cambridge Greensand Member (without counting teeth and the three femur morphotypes belonging to Ophthalmosauridae indet. which are described in Text S6) have been assigned to one of the five infrafamilial taxa that we could recognize. Whatever these taxa might be, the Cambridge Greensand Member provides one of the largest samples of a Cretaceous ichthyosaur assemblage, worldwide.

**Relative abundances.** We counted all diagnosable isolated bones and articulated specimens to estimate the relative abundance of each taxon in the Cambridge Greensand Member. Articulated specimens were counted only once in the total count. Despite their diagnostic features, we did not consider teeth as reliable bones for abundance counts because reptiles shed their teeth; therefore, the relative abundance of tooth morphotypes partly reflects ethological habits and/or physiological features, polluting the signal.

**Ecological diversity.** We used absolute tooth size, tooth shape, and tooth wear qualitatively to assess the ecological diversity of the ichthyosaurs from the Cambridge Greensand Member and the Marnes Bleues Formation. Intrinsic properties of teeth (size, shape) give an idea of the optimal range of prey that could be processed (e.g. [25,28]), whereas wear gives indications.
Diversity curves

The temporal evolution of two variables is analysed here: the taxonomic diversity at the specific and the generic levels. Both are simple counts of the parvipelvian taxonomic richness for each time interval (the stage level), from the Hettangian (Early Jurassic) to the Turonian (Late Cretaceous). The dataset compiled is available in Text S7. Stages characterize periods of Earth’s history with supposed rather constant climate, ocean dynamics, etc., but sometimes greatly differ in duration. Stage duration influences the number of specimens and thus the biodiversity. Rarefaction methods (e.g. [31]) cannot be employed here because numerous stages of Cretaceous record a very small number of specimens and should therefore be omitted from the analysis using this method. We divided the largest stages (Aptian and Albian) into their usual substages (lower and upper Aptian; lower, middle, and upper Albian), based on ammonite stratigraphy [32–38], rather than on the actual use of teeth by a single individual (e.g. [29,30]). A more detailed and quantitative analysis, encompassing numerous craniodental features of Jurassic and Cretaceous taxa is currently in preparation and will be published elsewhere.

Geological setting

The specimens that we have examined are classified by country, and then by formation. Geographic, stratigraphic (encompassing bio- and lithostratigraphic data) and paleoecological data (focusing on the vertebrate content) are given for each formation, when available. These data were taken from the literature and from collaborative investigations and/or personal field observations.

Gault Formation, UK. The Gault is a marl formation occurring in several basins of England, occurring in the East Midland Shelf, the Bedfordshire ‘Straits’, the Wessex Basin, the Wealden Basin, the Vectian Basin [47]; i.e. the whole eastern, southeastern and southern margins of England. The ‘Gault’ is also recognized as a facies in adjacent basins; for instance, it possibly occurs in the French Paris Basin [33,48,49]. The data presented below is restricted to the Gault Formation, cropping out in the UK, notably in Folkestone (Figure 1).

The Gault Formation encompasses most of the Albian, and passes laterally to the Cambridge Greensand Member/Upper Greensand Formation towards the east [32,47]. In the Cambridgeshire area, the Gault Formation is middle to late Albian in age, whereas its base extends up to the early Aptian (Tardejurasica Zone) in the Wealden Basin [32,47]. The fossil-rich locality of Folkestone lies within the Wealden Basin. Most of the Aptian–early Cenomanian English ichthyosaurs fossils studied here were collected during the 19th century as ‘coprolites’ and subsequently acquired by museums [50]; accordingly, there is no precise stratigraphic data linked to these specimens.

The studied specimens from this formation are from the NHMUK collection (19 specimens; see Text S1). Note that the few Gault Formation ichthyosaurs held at CAMSM appear to be lost; we have been unable to locate them in Sedgwick Museum or in the ‘stores’ at Cambridge University.

Upper Greensand Formation, UK. The Upper Greensand Formation is a glauconitic sandstone reworked from the Gault Formation [47,51]. The Upper Greensand Formation is distinct from the Cambridge Greensand Member. Both these deposits rework the Gault Formation, but they mostly occur in different basins (part of the Vectian and Wealden basins and part of the

Table 1. Bone morphotypes recognized here and their assignation.

| Bone     | Morphotype | Assignation               |
|----------|------------|---------------------------|
| Basiooccipital BM1 | 'Platypterygius' sp. | |
| Basiooccipital BM2 | Sistorina seeleyi | |
| Basiooccipital BM3 | Acamptonecetes sp. | |
| Tooth TM1 | 'Platypterygius' sp. | |
| Tooth TM2 | Sistorina seeleyi | |
| Tooth TM3 | Ophthalmosaurusinae indet. | |
| Humerus HM1 | 'Platypterygius' sp. | |
| Humerus HM2 | Sistorina seeleyi | |
| Humerus HM3 | Ophthalmosaurusinae indet. | |
| Humerus HM4 | 'Platypterygius' sp. | |
| Femur FM1 | 'Platypterygius' sp. | |
| Femur FM2 | Ophthalmosaurusidae indet. | |
| Femur FM3 | Ophthalmosaurusidae indet. | |
| Femur FM4 | Ophthalmosaurusidae indet. | |
| Femur FM5 | Cetarthrosaurus walkeri | |

The morphotype belong to Cetarthrosaurus walkeri is placed within the “Femur” category, as suggested by Seeley [106]. In the text, however, we opted for a more conservative position, considering this morphotype as a propodial, because of its unusual morphology.

The specific and generic curves are simple counts of the taxa that we (or the scientific community) recognize as valid for each time bin and the stratigraphic range of each taxa is based on oldest and youngest unambiguous fossil evidences, thus regardless of any phylogenetic ghost lineages. Lazarus ranges are, however, taken into account: for example, if taxon A occurs during the early Hauterivian and the late Aptian, then we consider taxon A as a valid Barremian and early Aptian taxon as well. The problematic genus Platypterygius was considered as a single taxon in the generic curves, grouping all species currently referred to it. The generic and specific diversity curves for the Jurassic are added to provide a point of comparison.

The specific and generic curves are simple counts of the taxa that we (or the scientific community) recognize as valid for each time bin and the stratigraphic range of each taxa is based on oldest and youngest unambiguous fossil evidences, thus regardless of any phylogenetic ghost lineages. Lazarus ranges are, however, taken into account: for example, if taxon A occurs during the early Hauterivian and the late Aptian, then we consider taxon A as a valid Barremian and early Aptian taxon as well. Diversity curves

The temporal evolution of two variables is analysed here: the taxonomic diversity at the specific and the generic levels. Both are simple counts of the parvipelvian taxonomic richness for each time interval (the stage level), from the Hettangian (Early Jurassic) to the Turonian (Late Cretaceous). The dataset compiled is available in Text S7. Stages characterize periods of Earth’s history with supposed rather constant climate, ocean dynamics, etc., but sometimes greatly differ in duration. Stage duration influences the number of specimens and thus the biodiversity. Rarefaction methods (e.g. [31]) cannot be employed here because numerous stages of Cretaceous record a very small number of specimens and should therefore be omitted from the analysis using this method. We divided the largest stages (Aptian and Albian) into their usual substages (lower and upper Aptian; lower, middle, and upper Albian), based on ammonite stratigraphy [32–38], rather than using temporal bins. The lower Aptian encompasses the ammonite zones from the oglandensis Zone to the jaciobi Zone; the upper Aptian from the subhomonocostatum Zone to the jacobi Zone; the lower Albian from the schrammeni/kandfuraeza Zone to the mammalitatum/amyrifrons Zone; the middle Albian to the dentatus Zone to the latius Zone; the upper Albian from the cristatum Zone to the dispar/brunnensi Zone. Using numerical ages from Kuhnt & Moulade [39], Ogg et al. [40], Scott [35] and Gradstein et al. [41], time bins for the stages/substages from the Hettangian to the Turonian have a mean duration 5.06 My, but the standard deviation remains quite high (±2.25 My). At any rate, these durations should not be considered too strictly as the error margin for many stage boundaries can reach ±1 My, and the numerical age for the substages of the Aptian and Albian are extrapolations based on the calculations of sedimentations rates between dated horizons [35,39]. Nevertheless, this permits to recover stage durations that are comparable. Moreover, this method of splitting the Aptian and the Albian is also useful for better understanding of the extinction of ichthyosaurs by providing a more precise evolution of ichthyosaur diversity near their extinction. But this approach does not mitigate other biases, such as collecting or environmental biases. Corrections exist for some of these factors [42–46] but this would move the results away from the ichthyosaur fossil record itself, an approach we are reluctant to undertake. This has the advantage of being intuitive and plotting ‘raw’ values, which are directly related to the fossil record itself and how we interpret it.

The specific and generic curves are simple counts of the taxa that we (or the scientific community) recognize as valid for each time bin and the stratigraphic range of each taxa is based on oldest and youngest unambiguous fossil evidences, thus regardless of any phylogenetic ghost lineages. Lazarus ranges are, however, taken into account: for example, if taxon A occurs during the early Hauterivian and the late Aptian, then we consider taxon A as a valid Barremian and early Aptian taxon as well. The problematic genus Platypterygius was considered as a single taxon in the generic curves, grouping all species currently referred to it. The generic and specific diversity curves for the Jurassic are added to provide a point of comparison.

Geological setting

Geographic, stratigraphic (encompassing bio- and lithostratigraphic data) and paleoecological data (focusing on the vertebrate content) are given for each formation, when available. These data were taken from the literature and from collaborative investigations and/or personal field observations.

Gault Formation, UK. The Gault is a marl formation occurring in several basins of England, occurring in the East Midland Shelf, the Bedfordshire 'Straits', the Wessex Basin, the Wealden Basin, the Vectian Basin [47]; i.e. the whole eastern, southeastern and southern margins of England. The 'Gault' is also recognized as a facies in adjacent basins; for instance, it possibly occurs in the French Paris Basin [33,48,49]. The data presented below is restricted to the Gault Formation, cropping out in the UK, notably in Folkestone (Figure 1).

The Gault Formation encompasses most of the Albian, and passes laterally to the Cambridge Greensand Member/Upper Greensand Formation towards the east [32,47]. In the Cambridgeshire area, the Gault Formation is middle to late Albian in age, whereas its base extends up to the early Albian ('Tardejurasica Zone') in the Wealden Basin [32,47]. The fossil-rich locality of Folkestone lies within the Wealden Basin. Most of the Aptian–early Cenomanian English ichthyosaurs fossils studied here were collected during the 19th century as 'coprolites' and subsequently acquired by museums [50]; accordingly, there is no precise stratigraphic data linked to these specimens.

The studied specimens from this formation are from the NHMUK collection (19 specimens; see Text S1). Note that the few Gault Formation ichthyosaurs held at CAMSM appear to be lost; we have been unable to locate them in Sedgwick Museum or in the 'stores' at Cambridge University.

Upper Greensand Formation, UK. The Upper Greensand Formation is a glauconitic sandstone reworked from the Gault Formation [47,51]. The Upper Greensand Formation is distinct from the Cambridge Greensand Member. Both these deposits rework the Gault Formation, but they mostly occur in different basins (part of the Vectian and Wealden basins and part of the
Zig Zag Chalk Formation. The Grey Chalk Group is strictly Melbury Marly Chalk Formation at the base, overlapped by the Chalk of previous authors is called the Grey Chalk Subgroup, the stratigraphy of the English Upper Cretaceous. The ‘Lower gland, East Anglia Massif) [47,51,52]. Hopson et al. [52] revised Bedfordshire ‘Straits’ area/Transitional Zone (i.e. central En-
figure 1), they are separated by an unconformity with the time-
formation in the collection database. Text S2 lists all ichthyosaur specimens from the Gault Formation and the ‘in-place’ early Cenomanian ones is probably small [53], although the base of this member is diachronous – as could be expected from such a transgressive/erosive deposit – becoming younger eastwards [58].

The Cambridge Greensand Member ichthyosaur material consists of several thousands specimens – mostly isolated teeth – and has never been reassessed thoroughly since Seeley’s catalogue, published in 1869 [50]. Specimens are housed in the CAMSM, GLAHM, IRSNB, LEICT, and NHMUK collections; see Text S3.

The Marnes Bleues Formation, France. The Marnes Bleues Formation was deposited during the Aptian and Albian in the Vocontian Basin [59]. The Vocontian Basin or Vocontian Trough was a deep, highly subsident Mesozoic basin located at the northwestern border of the Tethys, now southeastern France (Figure 2). It represents the deepest structural unit of the Dauphinois Basin, the Vercors carbonate platform representing its shallow part [60]. All southeastern France Albian ichthyosaur remains known so far were found in the Marnes Bleues Formation.

The Marnes Bleues Formation is a monotonous succession of grey marls with a significant lateral variation in thickness and local unconformities ([61,62]; V.F. & M.G., pers. obs.). Several local sandstone and limestone beds interrupt the sequence (e.g. [59,63]; V.F. & M.G., pers. obs.). Cephalopods are rare in this formation, and the age of the horizon of some specimens is only loosely constrained. In the Sisteron locality, two unconformities disturb the sequence: the upper Aptian lies on the truncated middle Aptian, and the last few meters of lower Albian (or the middle Albian) lie on the truncated upper Aptian via a 20 cm-thick glauconitic sandstone layer [59]; Figure 3). The specimens RGHP SI 1, RGHP SI 2, and RGHP SI 3 were found 2, 8, and 25 meters above the Aptian–Albian discordance, respectively, and are late early to middle Albian in age (Figure 3). In the Prads locality, the upper part of the Marnes Bleues Formation crops out, but a Quaternary terrace reworking sandstone clasts of the Oligocene Grès d’Annecy Formation truncates the top of the Marnes Bleues Formation. The specimen RGHP PR 1 was found 6.5 m below the base of the Quaternary terrace and is late Albian in age [64] (Figure 4). Text S4 lists all ichthyosaurs from the Marnes Bleues Formation studied in the present paper.

Referred material from other deposits. NHMUK R16 partim (teeth, Gault Formation); NHMUK R17 partim (teeth, Gault Formation); NHMUK R2890 partim (opisthotic, Gault Formation); NHMUK 47232 partim (teeth, Gault Formation); RHGP SI 2*, an incomplete skull, containing fragmentary snout and nasals, basioccipital, quadrate, opisthotic, supraoccipital, stapes, teeth from the middle Albian of Sisteron. At least three additional articulated specimens from the middle–late Albian of the Marnes Bleues Formation of the Vocontian Basin are present in the private collection of L. Ebbo [71].

Diagnosis. Platypterygiine ophthalmosaurid characterized by the following autapomorphies: basioccipital with raised process on the floor of foramen magnum; opisthotic with nearly absent paroccipital process (as in juvenile ’P. australis’ [26]); tooth with gracile crown and root with rectangular cross-section, the labiobuccal length being usually equal to one half of the anteroposterior length (less conspicuous in anterior- and posterior-most teeth).

Sisteronia seeleyi is also characterized by the following unique combination of features: elongated anterior process of the maxilla, reaching anteriorly the level of the nasal (unlike in Aegirosaurus [72]; Selciognathus insolitus [21]); prominent opisthotic facets on basioccipital (shared with S. insolitus [21]); expanded sacculus impression on opisthotic (shared with adult ’P. australis’ [11] and A. densus [20]); anteroposteriorly shortened quadrate condyle (shared with O. tenaciceps [73] and S. insolitus [21]); U-shaped supraoccipital (shared...
with ‘P. australis [11]; ‘P.’ hercynicus [18,74] and O. natans [75]); humerus with a facet for a posterior accessory element (shared with ‘P.’ hercynicus [74,76]; ‘P.’ americanus [14]; ‘P.’ sp. [16,77]; ‘Ophthalmosaurus monocharactus’ [78]).

Stratigraphic range. Early Albian–early Cenomanian (stratum typicum).

Geographic range. Eastern England basins (locus typicus), Vocontian Basin, France.

Note. As mentioned in the ‘Referred material from other deposits’ section, above, additional articulated specimens from the Albian of the Vocontian Basin are currently held in a private collection. These specimens were studied in the course of V.F.’s PhD thesis [71] and this information is crucial to establish the phylogenetic relationships of *Sisteronia*. Because this material cannot be used for the time being, we refrain from assessing the phylogenetic position of *Sisteronia* in this paper. These data and the phylogenetic placement of *Sisteronia* can be found in V.F.’s thesis [71]. However, as *Sisteronia* possesses numerous synapomorphies of platypterygiine ophthalmosauroids and lacks the synapomorphies of ophthalmosaurine ophthalmosauroids (see Anatomical Descriptions, below), we confidently place this taxon within Platypterygiinae.

**Description**

Measurements taken on CAMSM B58257_67 can be found in Table 2.

**Basioccipital (morphotype 2, see Systematic Paleontology above for a list of all specimens; Figure 5).** The basioccipital is roughly semi-circular in posterior view. As in *Sveltonectes* [21], the basioccipital is wider than high because of the prominence of the bulge-like opisthotic facet, the complete reduction of the extracondylar area ventrally, and the deep exoccipital facets. The extracondylar area is extremely reduced laterally (condyle width = 84.69% of the total width in CAMSM B57943) and...
There is no lateral ridge, unlike in *O. icenicus* 

...frequently subdivided by a deep anterolateral groove. This deep triangular facet facing posteroventrally for the basioccipital and a... 

...and resembles that of juvenile *'hercynicus'* [18,74]. The exoccipital facets are trapezoidal, tapering posteriorly, and are markedly concave. Partial otic impressions are preserved in RGHP SI 2; the impression for the posterior vertical semicircular canal is extremely deep. The utriculus ('utricular portion of labyrinth' of McGowan [79]) impression is a broad semicircular depression that is confluent with the impression for the posterior vertical semicircular canal dorsolaterally. Unlike in *P. australis* and *A. densus* [11,20], the impression for the anterior vertical semicircular canal is markedly reduced in length and depth and is separated from the rest of the otic impression by a lateral ridge.

**Parabasisphenoid (RGHP SI 2*; Figure 5).** The parabasisphenoid process is robust and extremely shortened, unlike that of ophthalmosaurine ichthyosaurs [20]. The condyle is oval and not flattened, and the notochordal pit is located ventral to the central point in most specimens. There is no ventral notch, but the ventral surface is flattened. The stapedial facet is not visible. The exoccipital facets are prominent and bordered medially and posteromedially by a prominent ridge. Both ridges meet medially and form a prominent process dividing the floor of foramen magnum in two in the transverse plane. In dorsal view, this ridge is wave-like and W-shaped. This structure appears ontogenetic, because the smaller basioccipitals have a reduced ridge. The anterior surface is flat and vertical, and the notochordal groove is shallow or absent. Two specimens (CAMSM B57948 and CAMSM B57954) have reduced opisthotic facets, a reduced exoccipital ridge, and deep dorsoventral grooves separating the basioccipital from the opisthotic facet, as in *P. australis* [11]. They are nevertheless closer to the *Sisteronia* morphology in general shape and are therefore included in this group.

**Ophistotic (CAMSM B57908; CAMSM B58077.78; CAMSM B58257.67* (holotype); CAMSM TN1753 parlim; NHMUK R2348; IRSNB GS10; NHMUK R2890 parlim; CAMSM ‘Saxon Cement works Cambridge 1912’; RGHP SI 2*; Figure 5).** The paroccipital process is robust and extremely shortened, unlike that of ophthalmosauromorph ichthyosaurs [20,73], and even shorter than in adult *P. australis* [11] and *P. hercynius* [74,76] and resembles that of juvenile *P. australis* [26]. There is no lateral ridge, unlike in *O. icenicus* and *A. densus* [20,73]. The opisthotic forms two facets medioventrally: a large, rugose, triangular facet facing posterolaterally for the basioccipital and a smaller, roughly triangular facet for the stapes. The stapedial facet is frequently subdivided by a deep anterolateral groove. This deep and narrow groove probably housed the hyomandibular branch of facial (VII) nerve or the glossopharyngeal (IX) nerve [73] and can be extremely complex in some specimens, such as NHMUK R2890, forming lateral spirals. The otic capsule impression has a deep and elongated impression for the horizontal semicircular canal, a wider and shorter impression for the posterior vertical semicircular canal, and a markedly expanded saccus, as in adult *P. australis* [11] and the holotype specimen of *A. densus* [20].

**Supraoccipital (RGHP SI 2*; Figure 5).** The supraoccipital is U-shaped with a ‘squared’ opening for the foramen magnum, similar to the condition in *P. australis* [11]. The exoccipital facets are trapezoidal, tapering posteriorly, and are markedly concave. Partial otic impressions are preserved in RGHP SI 2; the impression for the posterior vertical semicircular canal is extremely deep. The utriculus (‘utricular portion of labyrinth’ of McGowan [79]) impression is a broad semicircular depression that is confluent with the impression for the posterior vertical semicircular canal dorsolaterally. Unlike in *P. australis* and *A. densus* [11,20], the impression for the anterior vertical semicircular canal is markedly reduced in length and depth and is separated from the rest of the otic impression by a lateral ridge.

**Parabasisphenoid (RGHP SI 2*; Figure 5).** The parabasisphenoid process is markedly reduced and forms an elongated bulge on the lateral surface of the basioccipital. It is even more reduced than in *Siellemecetes*, where it forms a small protruding rod-like process [21], but it may be partly due to the strong diagenetic compaction of this bone in RGPH SI 2. The dorsal plateau appears kidney-shaped, as in *S. insolitus* [21] and unlike those of *Sveltonectes* [11]. The ventral surface of the basisphenoid bears a wide depression for the medial lamella of the pterygoid. The ventral carotid opening is set in the posterior half of the ventral surface. The posterior surface is divided by a deep median cleft, as in many post-Triassic ichthyosaurs (V.F., pers. obs. on NHMUK and CAMSM material). The parabasisphenoid is completely fused to the basioccipital in RGHP SI 2, suggesting a mature age [11], although the ontogenetic significance of this feature has been debated recently [26].

**Quadrate (CAMSM B58257.67*; RGHP SI 2*; Figure 6).** The quadrate is ear-shaped as in most ophthalmosaurids. The median surface is flat, and the stapedial articular facet is a deep depression bordered posteriorly and ventrally by a bony ridge. There is no evidence for a marked occipital lamella, unlike in *O. icenicus*, *P. australis* or *S. insolitus* ([11,21,73], respectively). The lateral surface is smooth and markedly concave. The short condyle is thick along its whole length, and rapidly tapers anteriorly, as in *O. icenicus* and *S. insolitus* [21,73]. The ventral surface of the condyle is concave anteriorly and becomes progressively flat posteriorly. The condyle is separated from the pterygoid lamella by a concave area. Similar quadrates occur in the Cambridge Greensand Member (e.g. CAMSM B57988; CAMSM B57989; NHMUK 35272 [two specimens]; IRSNB GS1; IRSNB GS6; IRSNB GS8), but the lack of clear-cut diagnostic feature prevents confident referral of these isolated bones to *Sisteronia seeleyi*; only the quadrates found in articulation with diagnostic elements are referred to the relevant taxa.

**Pterygoid (RGHP SI 2*).** A fragmentary pterygoid is preserved in RGPH SI 2. The dorsal lamella has a thick base, and the receptor pits for the basipterygoid process are unremarkable, unlike in *A. densus* [20].

**Articular (CAMSM B58257.67*; RGHP SI 2*; Figure 6).** The left articular is preserved. It appears distinct from that of other...
ichthyosaurs (e.g. *Ichthyosaurus communis* [79], *P. australis* [11,26], *O. icenicus* [80]) in being anteroposteriorly elongated (as in *Arthropygius chrisorum* [81]) and rectangular. It lacks the muscle attachment bulge seen *P. australis* and *Sveltonectes insolitus* [11,21].

**Dentition (morphotype 2; RGPH S1 2*; see Systematic Paleontology above for a complete list of specimens; Figure 6).** The teeth are straight generally much smaller than in other coeval taxa; the crown accounts for half of the total height in most teeth. Anterior and median teeth have a slender, straight, a conical crown with well-expressed apicobasal ridges and a markedly laterally compressed, yet quadrangular root. This is not a diagnostic artifact, because a large number of roots have resorption pits that remain perfectly circular and dozens of similar teeth are found in the Gault Formation and Cambridge Greensand Member. Posterior teeth have smaller and more robust crowns, and squarer root cross section. A smooth acellular dentine layer of cement, unlike in *Platypterygius* [82]. It is worth noting that quite similar teeth are found in a juvenile specimen of *P. australis* (NHMUK unnumbered). This may indicate close relationship between these two taxa and/or potential heterochronial processes related the tooth development.

**Centra (CAMSM B58257_67*; Figure 7).** A subtle ventral keel occurs on anterior thoracic centra, giving them a pentagonal shape. These centra have prominent diaophyses and parapophyses; horizontal bony ridges follow these apophyses posteriorly. Sacral and anterior caudal centra are weakly amphicoelous and have a circular outline.

**Scapula (CAMSM B58257_67*; Figure 7).** The medioventral part of the scapula is dorsoventrally compressed and widely expanded anteroposteriorly, to form the articulation area for the coracoid and the glenoid ventrally, and the acromion process anteriorly. Most of the medial part of the proximal surface is missing, so it is impossible to know if the scapular facet and the acromion process were continuous, as in *Ophthalmosaurus hercynicus* [74,76] and unlike *O. icenicus* [80,85] and *A. densus* [20].

**Humerus (CAMSM B58257_67*; CAMSM TN1757 partim; Figure 7).** The anterior surface of the shaft is rounded, whereas the posterior blade is acute and bordered by concave areas, giving the humerus a teardrop shape in cross-section. The deltopectoral crest nearly reaches the distal end of the humerus and merges with the ventral edge of the radial facet. Posterodistally, a bulge is present on the ventral side of the humerus, near the ulnar facet as in *Sveltonectes insolitus* [21] (but a dorsal bulge is also present in *Sveltonectes* [V.F., pers. obs.]). The humerus forms at least three distal facets: a large rounded radial facet, a longer (anteroposterior distance) but thinner (dorsoventral distance) ulnar facet, and a small triangular postaxial accessory facet. This condition has only been reported in some taxa referred to as *Platypterygius* (*P. hercynicus* [74]; *P. americanus* [14]; *P. sp.* [16,77]). All facets are rugose and concave. The anteroventral extremity of the humerus is damaged. Yet, the anterior edge of the radial facet is preserved, and the shape of the anterior surface of the humerus suggests that a facet for an anterior accessory epipodial element was also present.

from the abundant material in lower stratigraphic levels (the Gault Formation, the Upper Greensand Formation and the Cambridge Greensand Member). Therefore, pending a thorough reassessment of the species nested within *Platypterygius*, the material outside the chalk cannot be referred to *P*. *campylodon* unambiguously. Because phylogenetic and morphological analyses (e.g. [18,20,22]) indicate that *Platypterygius*, as currently defined, is a waste-basket, polyphyletic taxon, it cannot be used unambiguously at the moment either. Therefore, we opt here for a generic rank taxon, ‘*Platypterygius*’ sp., that groups large platypterygiine specimens that share similarities with ‘*P*. *hercynicus*’ and ‘*P*. *campylodon*’ sensu stricto. Detailed analysis of articulated material, such as the specimen described by Bardet [90], could further elucidate the anatomy, relationships and the taxonomic diversity of these large platypterygiine taxa from the Albian–Cenomanian of Eurasia. Because ‘*Platypterygius*’ sp. is based on numerous disarticulated remains, many of which are isolated bones, this taxon will not be counted as a distinct taxon in timebins where ‘*P*. *hercynicus*’ and/or ‘*P*. *campylodon*’ sensu stricto occur.

### Description

**Premaxilla (CAMSM TN283*; RGHP PR 1*; Figure 8).** The premaxilla is elongated and is impossible to distinguish from the dentary in the anterior-most part. Fossa praemaxillaris is shallow and ends anteriorly as a series of deep foramina. A network of very shallow grooves departing from these foramina textures the lateral surface of the very tip of the snout. The dental groove is deep, and the lingual wall is higher than the labial wall. Both these walls are greatly thickened ventrally. An intraosseous channel similar to the Meckelian canal of the dentary is present anteriorly.

**Nasal (CAMSM TN283*; RGHP PR 1*; Figure 8).** The nasal starts anteriorly as a thin plate covering the internal surface of the premaxilla, before emerging and forming the dorso medial surface of the rostrum. Unusually, the nasals interlock in a tongue-in-a-groove fashion in CAMSM TN283.

**Maxilla (CAMSM TN283*; Figure 8).** The maxilla is elongated and low. It emerges at the same level as the nasal in CAMSM TN283, thus differing from Kiprijanoff’s ‘*P*. *campylodon*’ material [91], and more posteriorly in RGHP PR 1, where there is no trace of a maxilla even in the posterior-most section of the rostrum. The medial part of the maxilla forms a very thick lingual wall posteriorly.

**Basioccipital (morphotype 1; see Systematic Paleontology above for a complete list of specimens; Figures 9, 10).** The basioccipital is spherical and usually of large size (except in CAMSM B57944). The condyle is large and markedly rounded and its peripheral edge is slightly flared. The median notochordal pit is teardrop-shaped and is located in the upper half of the condyle. It is sometimes accompanied by a narrow and shallow dorsoventral groove. The extracondylar area is extremely reduced, both ventrally and laterally (condyle width = 87.92% total width in CAMSM X50161). There is no ventral notch, and the extracondylar area is an oblique flat-topped ridge on the lateral surface of the basioccipital. There is no distinctive stapedial facet, and the opisthotic facet is a plateau the barely stands out (if at all) from the extracondylar area, unlike in *Sisteronia seeleyi*. The exoccipital facets are large, oval, slightly concave and lay directly on the body of the basioccipital, unlike in *Sisteronia seeleyi*, where the exoccipital facets are raised. The exoccipital facets are separated medially by a smooth and concave groove forming the base of foramen magnum. This groove is flattened in its middle part and then deepens anteriorly, forming a deep groove housing the nato chordal pit anteriorly. The anterior surface is oblique and flat or slightly convex.

This basioccipital morphotype belongs to a platypterygiine ophthalmosaurid, as indicated by the extremely reduced extracondylar area and lack of a peripheral groove around the condyle [20]. Within this clade, only the basioccipital of the genus *Platypterygius* is characterized by a reduction of the opisthotic facets, giving the basioccipital a perfectly circular shape in posterior view [11,90]. In some specimens (e.g. CAMSM B58250_56*), the floor of the foramen magnum is raised and appears very similar to that...
of ‘Platypertagus cf. kriprianoffi’ described by Bardet [90]. Others (e.g. CAMSM X50167) are concave, as in ‘P. hercynicus’ [76], but not as much as in ‘P. australis’ [11].

**Supraoccipital (CAMSM B58250_56*; Figure 10).** The supraoccipital is markedly U-shaped, as in ‘P. australis’ [11], ‘P. hercynicus’ [10,76], and *O. natans* [83]. The dorsomedial rod is oval in cross-section. Ventrolaterally, the supraoccipital forms an anteroposteriorly-expanded, brick-like eocoxipital process. The facet for the eocoxipital is flat, rectangular and posterovertebrally facing. The anterovertebral facet is set at a right angle to the eocoxipital facet and bears an impression for the otic capsule, probably the posterior vertical semi-circular canal. This condition differs from ‘P. australis’ [11], where a T-shaped impression housed the utricle as well. Unlike in ‘P. australis’ [11], the internal walls of the supraoccipital are smooth and do not bear any foramen.

**Dentary (CAMSM TN283*; RGHP PR 1*; Figure 8).** The dentary closely resembles the premaxilla, including the shape of the lateral fossa. The lingual wall of the dental groove is also higher than the labial wall.

**Rest of the mandible (CAMSM TN283*; RGHP PR 1*; Figure 8).** The splenial is the first bone to emerge from the rostrum. It starts anteriorly as a very thin pike of bone, before progressively forming the medial wall of the mandible posteriorly. The angular is long and crescentic in cross-section. It emerges at the level of the symphysis in CAMSM TN283. The surangular is boomerang-shaped in cross-section and emerges~50 mm after the angular in CAMSM TN283.

**Dentition (morphotype 1: see Systematic Paleontology above for a complete list of specimens; Figure 11).** The teeth are usually large; the height of the teeth from the middle part of the snout frequently exceeds 5 cm. The crown is conical, teeth are usually large; the height of the teeth from the middle part of the snout frequently exceeds 5 cm. The crown is wide, usually around 30° (but can reach 37° in some teeth of CAMSM B58010_27). Wide and smooth apicobasal ridges texture the acellular cementum ring. This texture is usually restricted on its apical third, but can cover the whole surface in some teeth. The apex possesses a pitted texture, as described in ‘Sisteronia seeleyi’ [90]. Others (e.g. *Sisteronia seeleyi*) have a high, usually short, and markedly oblique trochanter dorsalis (restricted to the proximal half of the humerus), as in some specimens of the ophthalmosaurine morphotype. The deltopectoral crest is high and forms a distal shallow ridge that merge with the ventral edge of the radial facet. Both trochanters are bordered by concave areas and give the proximal surface a concave parallelogram shape. The anterior edge of the humerus is rounded, whereas the posterior edge forms a very acute trailing blade, as in *Sisteronia seeleyi*. Unusually, this posterior edge is ‘trochanter-like’, being bordered by concave areas and thickening proximally to form a bulge on posterior end of the glenoid surface. The humerus possesses four distal facets, including two facets for accessory zeugopodial elements: one anteriorly and one posteriorly. Unusually, the posterior accessory facet is large, sometimes larger than the radial facet and faces posterodistally. The anterior accessory facet is the smallest; it is concave, roughly triangular, and faces anterodistally.

**Humerus (morphotypes 1 and 4; see Systematic Paleontology above for a complete list of specimens; Figure 12).** Humeri belonging to the second ‘Platypertagus’ sp. morphotype (humerus morphotype 4) have a high, usually short, and markedly oblique trochanter dorsalis (restricted to the proximal half of the humerus), as in some specimens of the ophthalmosaurine morphotype. The deltopectoralcrest is high and forms a distal shallow ridge that merge with the ventral edge of the radial facet. Both trochanters are bordered by concave areas and give the proximal surface a concave parallelogram shape. The anterior edge of the humerus is rounded, whereas the posterior edge forms a very acute trailing blade, as in *Sisteronia seeleyi*. Unusually, this posterior edge is ‘trochanter-like’, being bordered by concave areas and thickening proximally to form a bulge on posterior end of the glenoid surface. The humerus possesses four distal facets, including two facets for accessory zeugopodial elements: one anteriorly and one posteriorly. Unusually, the posterior accessory facet is large, sometimes larger than the radial facet and faces posterodistally. The anterior accessory facet is the smallest; it is concave, roughly triangular, and faces anterodistally.

The size, stoutness and distal architectural of these humeri correspond to those reported in taxa currently referred to as *Platypterygius* [14,16,76,77]. The humerus morphotype 1 presents a combination of features (large trochanters; large, flat and oval radial and unlar facet parallel to the sagittal plane; small to absent anterior accessory facet) that is only found in taxa currently referred to as *Platypterygius* from the ‘middle’ Cretaceous of Europe: ‘P. campylodon’ [91] and ‘P. platydactylus’ [95], although ‘P. australis’ possesses many similarities with these forms too [13]. The large four distal facets of the humerus morphotype 4 is a feature only found in some Aptian–Albian taxa currently referred to as *Platypterygius* as well: ‘P. hercynicus’ [74,76], and ‘P.’ sp. from North America [16,77]. Accordingly, we refer both morphotypes to ‘Platypterygius’ sp., but these morphotypes are likely to represent two distinct species.

**Manus (RGHP PR 1; Figure 13).** The manus is composed of tightly packed rectangular elements, as is typical for most platyperterygine ophthalmosaurids [20]. The manus architecture appears longipinnate (i.e. with a single digit arising from the intermedium) as in most species referred to as *Platypterygius* [2,13,14,74,76,84,95,96], *Sisteronia* (V.F. pers. obs. on uncurated...
material from southeastern France), and probably *Arthropterygius* [91,97].

**Femur (morphotype 1; see Systematic Paleontology above for a complete list of specimens; Figure 14).** As in *Sudetonectes insolitus* [21], the dorsal and ventral trochanter of the femur are very high and their morphology matches that of the humeri of ophthalmosauromorphs, by having a high, plate-like, and oblique dorsal trochanter separated from the slightly thicker ventral trochanter by a flattened area anteriorly. Both trochanters vanish at mid-length. The anterior surface is large and flat, and the posterior edge is rounded, giving the capitulum a rounded triangular shape in proximal or cross-section view. Distally, the femur forms three facets, as in many platypterygiines such as *Maiaspondylus* [22], *P. americanus* [14], *P. australis* [13] and *P. hercynicus* [76]. However, the extra facet is small, triangular and for an anterior accessory element. This condition has only been described in *P. australis* [13]; the other taxa have an extra facet either for a posterior accessory epipodial element or for the astragulus. The fibular facet is triangular and faces posterodistally. The square-shaped tibial facet is the largest and faces anterodistally.

Out of the several femora morphotypes recognized in the Cambridge Greensand member, only one can be attributed to *Platypterygius* sp. with confidence, thanks to an articulated specimen (CAMSM B58250_56) from the upper (chalky) part of the Cambridge Greensand Member. Moreover, similarly large and elongated femora with large trochanters, slightly rounded capitulum and three distal facets are only known in *P. hercynicus* [76] and *P. australis* [13].

**Systematic Paleontology**

Platypterygiinae indet.

1869 *Ichthyosaurus angustidens* Seeley [50]: 3
1869 *Ichthyosaurus honneyi* Seeley [50]: xvi
1869 *Ichthyosaurus platymerus* Seeley [50]: xvi

**Note.** As noted by Lydekker [98] and McGowan & Motani [69], Seeley [50] proposed the names *Ichthyosaurus honneyi, I. doughtyi, I. platymerus* and *I. angustidens* without a formal description or figure, making these taxa nomina nuda. However, we found the holotype specimens for each of these taxa in the CAMSM. Each were placed in a single box and clearly marked as being type specimens. This allows comparison of these taxa with the rest of the Albian record. Given the uncertain future of *Platypterygius* and its species [18], these taxa may therefore have priority over more recent ones, should they be found to belong to the same taxon. Accordingly, these taxa are regarded as nomina inquirenda, even if this. The holotypes of *I. angustidens* (CAMSM B20643, a partial tooth from the Lower Chalk of Hunstanton), *Ichthyosaurus honneyi* (CAMSM B58062, a femur from the Cambridge Greensand Member), and *I. platymerus* (CAMSM B38057, a humerus from the Cambridge Greensand Member) resemble *Platypterygius* sp. However, given the numerous issues inherent to *Platypterygius*, these species are considered as an indeterminate platypterygiine instead of *Platypterygius* sp. for the moment, pending a thorough reassessment of this genus.

Ophthalmosauromorpha Baur 1887 [66] sensu Fischer et al. [20].

**Ophthalmosauromorpha indet.**

Figure 15

1888 *Ophthalmosaurus cantabrigiensis* Lydekker [98]: 310
1889 *Ophthalmosaurus (?) cantabrigiensis* Lydekker [68]: 9 (NHMUK 35348)
1889 *Ichthyosaurus campylodon* Lydekker [68]: 19 (NHMUK R16)

2003 *Brachypterygius cantabrigiensis* McGowan & Motani [69]: 34: Figure 49

**Referred material from the Cambridge Greensand Member.** NHMUK 32140 partim (tooth); NHMUK R16 partim (tooth); NHMUK 47268 (5 teeth); CAMSM B58042 (humerus); CAMSM B58045 (humerus); CAMSM B58050 (humerus); CAMSM B58053 (humerus); CAMSM B58055 (humerus); CAMSM TN1727 partim (humerus); CAMSM TN1755 partim (2 humeri); IRSNB GS3 (humerus); LEICT G65.1991 (humerus); NHMUK R2843 (3 humeri); NHMUK R4513 (2 humeri); NHMUK 33348 (humerus); NHMUK 43989 (humerus, holotype of *Brachypterygius cantabrigiensis*); IRSNB GS60 (anterior accessory epipodial element).

**Referred material from other deposits.** NHMUK R16 partim (teeth, Gault Formation); NHMUK R17 partim (teeth, Gault Formation).

**Note.** Additionally, Fischer et al. [20] referred eleven basioccipitals, five stapes and one basiophenoid from the Cambridge Greensand Member to the ophthalmosaurine ophthalmosaurid *Acamptonectes* sp. Fischer et al. [20] misspelled the collection number of a basioccipital referred to as *Acamptonectes* sp.: in their paper, specimen CAMSM B56961 is actually CAMSM B57961. Now that additional ophthalmosauromorph ophthalmosaurids have been found in Cretaceous strata of Eurasia [99], the referral of these remains to the Hauterivian genus *Acamptonectes* by Fischer et al. [20] is disputable, even if one basioccipital (CAMSM B57962) and one basiophenoid (NHMUK PV R2341) exhibited autapomorphic features of *Acamptonectes*. Accordingly, we refer all these *Acamptonectes* sp. remains (i.e. CAMSM B57955 [basioccipital], CAMSM B57949 [basioccipital], CAMSM B57942 [basioccipital], CAMSM B57952 [basioccipital], CAMSM B56961 [basioccipital], CAMSM TN1735 partim [basioccipital], CAMSM TN1751 partim [basioccipital], CAMSM TN1753 partim [basioccipital], CAMSM TN1755 partim [basioccipital], GLAHM V.1463 [basioccipital, Newmarket road pits], NHMUK 35301 [basioccipital], CAMSM B58074 [stapes], CAMSM B58075 [stapes], CAMSM B58079 [stapes], CAMSM TN1757 partim [stapes], GLAHM V.1535/1 [stapes], NHMUK R2341 [basiophenoid]) to Ophthalmosaurinae indet. The holotype of *I. cantabrigiensis* (NHMUK 43989) lacks distinguishing features from other ophthalmosaurines; accordingly, this taxon is considered here as nomen dubium.

**Description**

**Dentition (morphotype 3; see Systematic Paleontology above for a complete list of specimens; Figure 15 A, B).** The teeth are recurved medially. The crown is conical, textured by light apicobasal ridges, and appears small compared to the apicobasal height of the tooth (19% in NHMUK 47268 partim). The apex is pointed and smooth. Both the acellular cementum ring and the root are smooth (no apicobasal ridges) and their cross-section is rounded. Some teeth have slightly flattened surface of on their roots, but lack the well-defined angles seen in the other tooth morphotypes (*Platypterygius* sp. and *Sisteronia seeleyi*).

A squared root section is a synapomorphy of platypterygine ichthyosaurs [20] (but reversed in *Aegirosaurus* [1,100]). This tooth morphotype does not correspond to *Aegirosaurus* [1], being recurved, having a much smaller crown and a smooth apex. This tooth morphotype is however similar to that of *Ophthalmosaurus incurvus* [73]. Accordingly, we refer the tooth morphotype 3 to Ophthalmosaurinae indet.

**Humerus (morphotype 4; see Systematic Paleontology above for a complete list of specimens; Figure 15 C).** The humerus is usually small and stout; but larger specimens (such as...
CAMS TN1755 partum) have a more slender shape. The short trochanter dorsalis and the deltopectoral crest are well developed, although the latter may be reduced in some specimens. A similar variability has already been reported in the ophthalmosaurine A. densus [20]. The humerus forms three distal facets that are sub-equal in size. The posterior-most (ulnar) facet is markedly deflected posterolaterally and has a concave margin in dorsal view. The median (radial) facet is the largest and squared or slightly dorsoventrally elongated. The anterior-most (accessory) facet is often slightly deflected anterolaterally.

This humerus morphotype has been interpreted in various ways since Lydekker [68,96]. He considered this three distal facets as indicative of Ophthalmosaurus, but the equal size of these three facets in one of these humeri, NHMUK 43989, differed from O. tenuissimus, justifying a new species, Ophthalmosaurus cantabrigiensis. Then, McGowan & Motani [69] considered this species to belong to Brachypterygius, mainly because it did not resemble O. tenuissimus enough and because they already inferred the presence of Brachypterygius in the Cambridge Greensand Member using bacteriuran evidence. Evidence for a referral of this humerus morphotype to Brachypterygius is, however, poor. Indeed, the largest facet on this humerus morphotype (to which the holotype of O. cantabrigiensis belongs) is the ‘median’ facet, a condition never observed in any ichthyosaur whose intermediate contacts the humerus: in these ichthyosaurs, the intermediate facet is less than half the size of the radial or the ulnar facets (B. extremus [73,101]; pers. obs. on holotype NHMUK R3177; Aegirosaurus [72]; Mainspondylus [15]); a similar interpretation for these morphotype 3 humeri would imply an enormous intermediate, larger than both the radius and the ulna, a condition never seen in Ichthyosaurus. Moreover, the radial and ulnar facet are both invariably markedly deflected outwards in the above-mentioned taxa (ibid.), whereas only the ulnar facet is consistently deflected outwards (posterolaterally) in the humerus morphotype 3, as in ophthalmosaurine ichthyosaurs [20]. Kear & Zammit [26] recently casted doubt on the validity of this character by studying two in utero specimens that they referred to the platyspondyine taxon ‘Platypterygius’ australis, which presumably exhibited the same morphology. However, it is clear that the ossification of the humeri that they figure is far from complete ([26];Figure 2); thus their shape cannot be assessed unambiguously; moreover, adults representatives of this taxon do not exhibit this peculiar morphology [13]. The degree of deflection of the anterior facet forms a wide spectrum in humerus morphotype 3 (ophthalmosaurine), within which only some (usually small) specimens such as NHMUK 43989 (holotype of O. cantabrigiensis), CAMSM B58055, and CAMSM TN1727 partum have a slightly anterolaterally deflected anterior facet. This is likely a juvenile condition that disappears with ontogeny, as in P. australis [26]. Moreover, some specimens of adult ophthalmosaurines also show a slightly deflected anterior facet (e.g. GLAHM 132855, holotype of O. densus; LEICT G1.2001.016, Ophthalmosaurus sp.; GLAHM V1070, Ophthalmosaurus tenuissimus [20]; V.F., pers. obs. on GLAHM, NHMUK, MJML, and CAMSM material). Similarly, the relative size of the anterior facet in ophthalmosaurines also forms a wide spectrum (e.g. [80,83]; V.F., pers. obs. on GLAHM, NHMUK, MJML, and CAMSM material) within which the holotype of O. cantabrigiensis falls satisfactorily. Therefore, we consider the evidence for a referral of this morphotype to Brachypterygius as unfounded, and that its morphology falls within the known spectrum for ophthalmosaurines ophthalmosaurids and lacks autapomorphies in the current state of our knowledge. Accordingly, we refer this morphotype to Ophthalmosaurinae indet.

Epipodium (IRSNB GS60; Figure 15 D). IRSNB GS60 is an anterior accessory epipodial element of a forefin. It is elongated proximodistally. This element bears facets for humerus, radius, radiale, and the first autopodial element of the anterior accessory digit. The radial facet is the largest and the humeral and radial facet are large and equal in size. The humeral and radial facets form a 90° angle. The anterior surface is saddle-shaped rather than convex or flat and its overall shape is not crescent-like. The dorsal half is much thicker than the ventral half.

Accessory epipodial elements are frequent in ophthalmosaurids, but they greatly differ in shape (compare [2,21,77,102]). IRSNB GS60 appears strikingly similar to that of many large specimens of Ophthalmosaurus tenuissimus (V.F., pers. obs. on GLAHM, NHMUK, MJML, and CAMSM material). The lack of a crescentic shape differs from the anterior accessory epipodal element of Scelionetes insidiosus and the pisiform of P. americanus [14] and the combination of a proximodistal elongation+ a large humeral facet+ three additional facets differs from all other platyspondyine ophthalmosaurids for which the epipodium is known [13,16,77,102]. We interpret IRSNB GS60 as an ophthalmosaurinae anterior accessory epipodial element because that morphology has only been found in O. tenuissimus and in the poorly known but probably closely related ‘Paraphthalmosaurus’ [103] (V.F. pers. obs. on holotype in SSU) and ‘Tayskovia’ [104] so far. Both of these are considered as junior synonyms of Ophthalmosaurus by Maisch & Matzke [105] and McGowan & Motani [69].

Systematic Paleontology

Ophthalmosauridae indet.

1869 Ichthyosaurus doughtyi Seeley [50] : xvi

Note. The holotype of I. doughtyi (CAMS B58044, from the Cambridge Greensand Member) is a partial humerus, belonging to a juvenile ichthyosaur. The presence of a preaxial accessory facet allows assignment to Ophthalmosauridae, but this specimen lacks diagnostic features. It is therefore referred to Ophthalmosauridae indet. and Ichthyosaurus doughtyi is regarded here as a nomen dubium. Several other propodials cannot be assigned more precisely than Ophthalmosauridae indet. These morphotypes are described in Text S6.

Ichthyosaurus insertae sedis Cetarthrosaurus walkerii Seeley, 1873 [106] (Seeley, 1869 [50])

Figure 16

Holotype. CAMSM B58069, a propodial from the Cambridge Greensand Member (Lower Chalk Formation), early Cenomanian, but phosphatized and reworked from the top (late Albian) of the Gault Formation.

Referred material. CAMSM X50170, from the same age and locality as the holotype.

Emended diagnosis. Cetarthrosaurus walkerii possesses the following autapomorphies within Ichthyosaurus: propodial with hemispherical capitulum disconnected from dorsal and ventral trochanters; elongated and slender shaft (axial length/mid-shaft width ratio > 2.93 in holotype and 3.00 in referred specimens); sheet-like ventral trochanter parallel to the long axis.

Additionally, among Ichthyosaurus, the combination of a three-faceted propodial, including a small facet for a preaxial accessory element and a distally-facing ulnar/tilbar facet is only shared by: one femur of Simopherygius quadriscissus [86], humerus and femora of some specimens of ‘Platypterygius’ sp. from England (this work), humerus and femora of P. australis [13]; humerus of Cayptulicosaurus [107]; an unnamed taxon from Canada [23].

Occurrence. Late Albian of the Gault Formation reworked in the Cambridge Greensand Member. No evidence for presence
in the upper (early Cenomanian) part of the Cambridge Greensand Member.

**Note.** The holotype of *C. walkeri* (CAMSM B58069) was described by Seeley \[50,106\] as a right femur of very unusual shape. Seeley first named *walkeri* as a new species of the genus *Ichthyosaurus* \[50\]. But his comparison of the propodial with other ichthyosaurs and cetaceans led him to propose a new generic referral for this specimen four years later \[106\]. Later, this taxon was considered as a mosasaurid (Hulke *in* Lydekker \[98\]; \[3\]) and disappeared from the literature. McGowan & Motani’s review \[69\] considered *I. walkeri* as a nomen dubium without discussion and did not mentioned *Cetarthrosaurus*.

During this study, a small right propodial (CAMSM X50170, marked as ‘*Ichthyosaurus humerus, Cambridge Greensand, Cambridge*’) and strikingly similar to CAMSM B58069, was found. It shares all the peculiar features of the holotype of *Cetarthrosaurus walkeri*, but its dorsal surface is less eroded, allowing a better description of that peculiar propodial morphotype. Despite its unusual shape, this propodial is clearly ichthyosaurian (contra Hulke *in* Lydekker \[98\]). The presence of three distal facets suggests relationship with Ophthalmosauridae, but at least one specimen of the basal baracromian *Stenopterygius* is known to have three distal facets on its femur as well \[86\]. Moreover, the hemispherical capitulum separated from dorsal and ventral trochanter is unique among post-Triassic ichthyosaurs. Yet, this propodial is diagnostic and, therefore, the taxon *Cetarthrosaurus walkeri* must be considered as a valid, albeit poorly known, late Albian ichthyosaur.

**Description**

*Cetarthrosaurus* is only known from two propodials (Figure 16). Their shape is so unusual that is difficult to decipher the limb they belong to. Accordingly, we describe them as propodials and compare them to humeri and femora of neoichthyosaurs. The shaft of the propodial is constricted and elongated (axial length/anterdistal length = 64.52 mm/33.35 mm = 1.93 in the holotype and 61.19 mm/27.51 mm = 2.22 in CAMSM X50170) and the capitulum is hemispherical. Both the anterior and the posterior surfaces of the shaft are saddle-shaped, but the anterior one is flatter (whereas it is markedly flat or concave in ichthyosaurs \[69\]).

The dorsal trochanter is extremely high: its height is more than 80% the height of the capitulum (even the femur having the largest dorsal trochanter of the CAMSM greensand material [CAMSM B58059] has a ratio of 56.7%, because the capitulum of ophthalmosaurids is usually much larger than that of *C. walkeri*). The dorsal trochanter is oblique, only slightly plate-like (i.e. the dorsal surface is not flat-topped but oblique and bordered by concave areas; this condition is therefore ‘intermediate’ between basal thunnosaurians and ophthalmosaurids), and extends up to the distal edge of the propodial through a shallow ridge confluent with the dorsal edge of the anterior accessory facet. The ventral trochanter forms a prominent, long, and sheet-like axial ridge bordered by concave areas. Unusually, these trochanters do not

![Figure 16. *Cetarthrosaurus walkeri*, propodials. A–F: Holotype (CAMSM B58069), in proximal (A), distal (B), dorsal (C), anterior (D), posterior (E), and ventral (F) views. G–L: referred specimen (CAMSM X50170), in proximal (G), distal (H), dorsal (I), anterior (J), posterior (K), and ventral (L) views. Note the high aspect ratio, the rounded capitulum disconnected from the shaft trochanters, and the high and lamellar dorsal trochanter. Abbreviations: AAE: anterior accessory epipodial element; Fi: fibula; Ra: radius; Ti: tibia; Ul: ulna.](10.1371/journal.pone.0084709.g016)
merge with the capitulum, as noted by Seeley [50]. Distally, the propodial has three concave facets: a small anterior accessory facet, and two large squared facets for radius/tibia and ulna/fibula. The radial/tibial facet faces distally and the ulnar/fibular facet faces posterodistally.

### Diversity curves

The taxonomic diversity of Cretaceous ichthyosaurs is now significantly higher than hypothesized a few years ago (Figure 17). The Berriasian diversity has been increased because of the recognition of Late Jurassic ichthyosaurs in this stage: Caypullisaurus bonapartei [108,109], Aegirosaurus sp. (as a Lazarus taxon [1]) and cf. Ophthalmosaurus [20]. Despite the description of new fossils from the Valanginian and Hauterivian from western Europe, these stages are still inadequately known, and constitute a ‘diversity low point’ for the Cretaceous. Indeed, the number of specimens known from this interval is extremely low: RGHP LA 1 is the first diagnostic ichthyosaur reported from the Valanginian [1], and only of handful of ichthyosaur specimens are known from the Hauterivian [19,20,110].

**Figure 17. Stage-level taxonomic diversity of Cretaceous ichthyosaurs compared to previous assessments; the number of genera has dramatically increased since year 2002.** The position of each stage on the X-axis is proportional to its duration. The grey line represents the generic diversity as of 2002. See Text S7 for the dataset. doi:10.1371/journal.pone.0084709.g017

**Figure 18. Evolution of ichthyosaur taxonomic richness during the Jurassic and Cretaceous.** The Aptian and Albian are split in two and three substages, respectively. The generic curve (black) considers *Platypertegius* as a single taxon. See Text S7 for the dataset. doi:10.1371/journal.pone.0084709.g018
Diversity explodes during the Barremian, with the recognition of several platypertygine ophthalmosaurids such as *Sveltonectes insolitus* and *Simbriskasaurus bifidus* from western Russia [21,111], *P*. *sachalinus* [112] and *P*. *haukeli* [113,114] from South America, in addition to *Malawania anachronus* from Iraq [19]. The diversity diminishes during the Aptian (Figures 17, 18), probably because of sampling and taxonomic biases, because only a handful of diagnostic Aptian ichthyosaurs have been recovered worldwide [93,99]. Then, the diversity becomes very high during the Albian. The generic curve remains rather constant because *Platypterygius* was considered as a single entity in this curve; if recent advances regarding the polyphyly and status of *Platypterygius* [18,22,111] are taken into account, it is even possible that the generic taxonomic richness will equal the specific one and reach a value of 10 during the Albian, as suggested by yet unpublished analyses [71]. Splitting the Aptian and the Albian (Figure 18) does not change the picture, but indicates that a high diversity (eight species) is restricted to the late Albian. Comparable parvipleuran ichthyosaur diversity has only been reported in the early Toarcian Lagerstatten of western Europe, where five genera and as many as eleven species have been reported [69,105,115–119], and the Tithonian strata of South America, Germany, England, and Russia, containing seven species and four genera [72,103–105,107,120–128]. The ichthyosaur diversity then severely drops during the Cenomanian and reaches zero by Turonian times.

The taxonomic diversity of Cretaceous ichthyosaurs is now equivalent to or greater than that of their Jurassic ancestors, both at the generic and specific levels, contrary to previous assumptions [4,129,130]. Indeed, the diversity frequently reaches four to five genera and seven to eight species whenever fossil-rich sediments occurring in distinct basins are found, such as the Hettangian–Sinemurian [69,131–135] of western Europe, the Tithonian of England (top of the Kimmeridge Clay Formation; [136,137]), Germany [72,100,138,139] and South America [107,108,140], and several periods during the Albian [22]. The extremely abundant material from the Toarcian (possibly several thousands of specimens [141]) certainly biases the record. A ‘safer’ interpretation of these fluctuating curves is to consider the diversity of ophthalmosaurids was possibly rather constant from their initial Middle Jurassic radiation onwards and only dropped severely at the beginning of the Late Cretaceous.

**Discussion**

The Albian ichthyosaurs from western Europe

In his Catalogue, Seeley [50] named four new species from the Cambridge Greensand Member: *Ichthyosaurus walkeri*, *Ichthyosaurus doughertyi*, *Ichthyosaurus bonneyi*, and *Ichthyosaurus platymerus*. He did not figure the specimens, nor did he designate holotypes, and only formally described a cast of the holotype specimen of *I. walkeri*. Only *I. walkeri* was subsequently re-described, figured, and made the type species of a new genus, *Cetarthrosaurus* [106], a rare decision at that time. Lydekker [98] and McGowan & Motani [69] considered Seeley’s three other species as invalid, being nomina nuda. However, specimens CAMSM B58044, CAMSM B58057, CAMSM B58062 are clearly marked as holotype specimens of *I. doughertyi*, *I. platymerus*, and *I. bonneyi*, respectively; this permits comparison of these specimens with other material and assessment of their validity. Lydekker [98] named *Ophthalmosaurinus canadensis* on the basis of a left humerus (NHMUK 43989) from the Cambridge Greensand Member. McGowan & Motani [69] considered this humerus as indicative of the presence of *Brachypterygius* (B. *canadensis*) in the Cambridge Greensand Member, because they interpreted the large median facet as a facet for the intermediate. Yet, they also noted the presence of basioccipitals and humeri referable to *Ophthalmosaurinus* in the same member.

Our analysis indicates the presence of three common and distinct taxa represented by numerous diagnostic bones (Table 1): *Platypterygius* sp., *Sictornia seeleyi*, Ophthalmosaurinae indet., and an additional but rare taxon: *Cetarthrosaurus walkeri*. Appendicular bones such as humeri and femora, which appear to be more interspecifically variable within ichthyosaurs, even suggest a higher diversity, and probably reflect the specific diversity. *Ichthyosaurus doughertyi* is an indeterminate ophthalmosaurid. *Ichthyosaurus bonneyi* and *Ichthyosaurus platymerus* are not diagnostic and can be referred to as *Platypterygius* sp., and *Brachypterygius cantabrigiensis* is an indeterminate ophthalmosaurine ophthalmosaurid, which supports Lydekker’s [98] opinion, given the state of knowledge at his time. Therefore, there is no solid evidence for the presence of *Brachypterygius* in the Cretaceous of Europe. The previous stratigraphic range of *Brachypterygius* (Kimmeridgian–Albian) was one of the main reasons why Ensom et al. [142] associated a fragmentary skeleton from the Berriasian of England to this genus; our data suggest this referral is not substantiated.

*Platypterygius hercynicus* in coeval deposits from northwestern France [18] should be added to the assemblage described above. Many isolated bones from the Cambridge Greensand Member also closely resemble *P.* *hercynicus* but cannot be attributed to this species unambiguously. The humerus morphotype 4 morphotype, exhibiting four distal facets has only been reported in *P.* *hercynicus* [74,76] and two *Platypterygius* sp. specimens from North America distinct from *P.* *americanus* [16,77]. Some basioccipitals (with a raised floor of foramen magnum), teeth, and femora (with three distal facets including one probably for the astragalus) are also identical to that of *P.* *hercynicus* (see [74,76]).

Additionally, the two identified humeral morphotypes here referred to *Platypterygius* sp. indicate that another large platypterygine roamed western Europe; this second taxon may correspond to *Ichthyosaurus hauthali* [21,111] from South America [21]. It is therefore impossible in the current state of our knowledge to have an idea of the variability of these features. Yet, femora from the Cambridge Greensand Member still augments this diversity of femoral morphologies of ophthalmosaurids, by having five different morphotypes (Table 4; Text S6). This disparity may therefore indicate that more than four ichthyosaur taxa co-habited the ecosystem of the Cambridge Greensand Member, as suggested by humerus evidence.

In terms of relative abundances (Figure 19), *Platypterygius* sp. represents only 33% (41 specimens) of the assemblage. Ophthalm-
mosaurinae accounts for 33% of the assemblage (41 specimens as well). *Sisteronia seeleyi* represents 32% (40 specimens) of the assemblage, and *C. walkeri* completes the picture with a relative abundance of 2% (2 specimens). These proportions contradict the popular belief of monogeneric (*Platypterygius*) ichthyosaur assemblages in the Cretaceous (e.g. [4,5]). Moreover, the count of *Platypterygius* sp. is probably overestimated relatively to other taxa because this taxon (and possibly *C. walkeri*) is the only one to which one femoral morphotype has been tied, increasing the number of referable specimens, whereas the femora of Cretaceous ophthalmosaurus and *Sisteronia seeleyi* are yet unknown. Similarly, the count for *C. walkeri* may be underestimated, because only two propodials are referable to this poorly known taxon. It is even possible that the femora of *C. walkeri* belong to one of the other ichthyosaur taxa recognized here, but this could only be proven with articulated material. On the subfamilial level, however, *Platypterygiinae* dominates the assemblage with a relative abundance of 65% versus 33% for Ophthalmosaurinae.

The ichthyosaur assemblage of the Cambridge Greensand Member, containing four co-occurring genera, is the most diversified assemblage ever reported in a single sedimentary body of Cretaceous age. The persistence of *P. hercynicus* in the latest Albian of northwestern France and possibly Cambridge area and the co-occurrence of large *Platypterygius* sp. and *Sisteronia seeleyi* in the Vocontian Basin suggest that western Europe was a diversity hot-spot for Albian–earliest Cenomanian ichthyosaurs, a few million years prior to their final extinction, at the Cenomanian–Turonian boundary [3].

Preliminary assessment of the marine reptile assemblage of a new latest Albian–earliest Cenomanian locality in western Russia (V.F., pers. obs. on SSU material) suggests a similar diversity in this deposit as well, with the presence of at least three ichthyosaur taxa, including platypterygiines and ophthalmosaurusines, and with distinct tooth morphologies. Articulated material is needed for a better understanding of these forms, but this suggests a high diversity in ichthyosaurs of the Albian–Cenomanian boundary in western Russia as well. This situation appears similar to the Lower Albian of Canada, where three to four taxa have recently been recognized [15,16,22,23] and markedly contrasts with the monospecific ichthyosaur assemblages in the Albian of Australia [12,13] and U.S.A. [22], despite the fact that a large number of specimens have been discovered in numerous localities, at least in Australia. Therefore, whereas the taxonomic richness of late Albian ichthyosaurs now reaches eight species (Figure 18); and probably as many genera if *Platypterygius* is split according to recent revisions [18,111]), this diversity shows a strong geographical variability and was not uniformly high worldwide.

Beta diversity is more difficult to assess, as most Cretaceous ichthyosaur localities have yielded a handful of specimens, at best. Even if the Albian record is generally better than that of the rest of the Cretaceous, the Albian ichthyosaur localities are not contemporaneous. Nevertheless, Albian ichthyosaurs appear to have their biogeographical ranges limited to a regional scale; indeed, not a single species is shared between the Australia, North American, Canadian and European provinces, suggesting a high beta diversity. At a smaller geographic scale, ichthyosaur assemblages appear similar, as suggested by the French and eastern England localities described above. It is nevertheless possible that the apparent endemism between the major Albian ichthyosaur provinces is due to poor sampling. Indeed, late Albian ichthyosaurs of western Europe have similarities with the early Albian Canadian assemblage: *P. hercynicus* is northwestern France and similar *Platypterygius* sp. remains in the Cambridge Greensand Member resemble the large but poorly preserved *Platypterygius* sp. described by Maxwell & Caldwell [16], having a similar humerus and forefin. Furthermore, at least one isolated ilium from the

Gault Formation [NHMUK unnumbered] matches that of *Athabascarasaurus bitumineus* from the early Albian of Canada [22,23], being markedly recurved posterodorsally. A better knowledge of the teeth and basicranium of the Canadian taxa could help to assess their presence or absence in Eurasian ecosystems.

**Ichthyosaur-dominated ecosystems in the late Early Cretaceous of Europe**

Tooth size and shape varies greatly among ichthyosaur taxa in the Cambridge Greensand Member. *Platypterygius* sp. possesses the largest and most robust teeth: the conical crown is robust, and the numerous apicobasal ridges texturing the crown, the acellular cementum ring and the root likely reinforced the resistance of the teeth under dorsoventral stress, as in corrugated materials. *Sisteronia seeleyi* possesses the smallest and most gracile teeth: the crown is pointed and slender, the tooth lacks conspicuous apicobasal ridges basally to the crown, and the root is slender and markedly compressed transversely. Ophthalmosaurinae indet. falls in between these extremes.

Wear patterns are similarly contrasted between *Platypterygius* sp. and *Sisteronia seeleyi*. *Platypterygius* sp. teeth are by far the most worn: the majority of isolated (possibly shed) teeth fall within the most severe category of wear (apex broken and polished), and articulated specimens show a large proportion of functional teeth belonging to this wear category as well (e.g. CAMSM TN283; RGHP PR 1). By contrast, nearly all *Sisteronia seeleyi* teeth are only slightly polished or still have pristine enamel texture on the apex. Articulated rostra of *Sisteronia seeleyi* are currently not available, preventing statistical wear analysis on functional teeth. Similarly, very few ophthalmosaurine teeth occur in the Cambridge Greensand Member, preventing any evaluation of their wear with confidence. Yet, preserved ophthalmosaurine tooth apices belonging to all categories of wear are found within this small assemblage.
This situation, where the most robust teeth are also the most worn and vice-versa, suggests contrasted diet for these taxa. These shape and wear differences also match size differences (Figure 20).

Accordingly, we propose that these ichthyosaurs colonized distinct feeding guilds: *Platypododon interruptus* sp. probably belongs to a guild of top-tier predators, possibly feeding on tetrapods (among other prey), given the robust tooth shape and the intense tooth wear with frequent apical tooth breakage and enamel spalling, as already suggested for *P. australis* [10]. These features are regarded as indicative of such diet in marine crocodyliforms too [114]. Ophthalmosaurusines are considered as opportunistic generalists, because their tooth shape and wear closely resembles those in *Aegirosaurus* and adult *O. icenicus*, considered generalists [1,99]. The delicate, slender and unworn teeth of *Sisteronia seeleyi* suggest that it belongs to a 'pierce'-oriented guild, feeding on soft and small prey such as small fishes and neocoleoid cephalopods, according to Massare's criteria [25,28] (Figure 20). These ichthyosaurs therefore occupied up to three feeding guilds within the single ecosystem of the upper Gault Formation/ Cambridge Greensand Member, despite the presence of a diversified plesiosaur assemblage including the gigantic plesiosaur *Polyptychodon interruptus* [50,68,144]. The presence of ichthyosaurs at several levels of the trophic chain of one ecosystem has not been previously reported from assemblages dating to after the Early Jurassic, when ichthyosaurs dominated the ecosystems of the European archipelago [24,25,119,145] together with several plesiosaur taxa, including large rhomaleosaurids [146–151]. The fact that ichthyosaurs from the late Albian-early Cenomanian deposits of Europe and possibly Russia, like their Early Jurassic ancestors, colonized multiple ecological niches despite the presence of numerous other marine reptile taxa shows that the 'last' ichthyosaurs were still a diversified and important component of the marine ecosystems up to a few millions years prior to their extinction, at least in Europe and Russia.

**Conclusions**

The thorough analysis of the diversity of the rich ichthyosaur assemblages of middle Albian–earliest Cenomanian of England and southern France yields the following results:

1. We recognize four taxa as valid: *Platypododon interruptus* gen. et sp. nov., *Ophthalmosaurus icenicus* indet., and *Cetartiodactylus walkerii*. We consider *Ichthyosaurus dougthyi*, *Ichthyosaurus bonneyi*, *Ichthyosaurus platynemus*, *Ichthyosaurus angustidens* and *Brachypterygius catanbriensis* as invalid; there is no solid evidence for the presence of *Brachypterygius* in the Cretaceous.

2. Ichthyosaurs occupied several feeding guilds within the mid-Cretaceous ecosystems of western Europe: *Platypododon interruptus* sp. likely occupied apex predator along with the large plesiosaur *Polyptychodon interruptus*, *Sisteronia seeleyi* occupied a 'pierce'-oriented guild, and ophthalmosaurusine ophthalmosaurids probably occupied a 'generalist/opportunist' guild.

3. These high taxonomic richnesses and strong ecological presences occur a few million years prior to the final extinction of ichthyosaurs. This indicates that the 'last' ichthyosaurs were diversified and were still a major component of marine ecosystems, contradicting previous views of ichthyosaur evolutionary history. The alpha diversity of ichthyosaur is, however, highly variable between provinces. This new data provides a whole new context to analyze the extinction of ichthyosaurs.
