ABSTRACT

Acute Coronary Syndromes (ACS) represent the most common cause of death in the western world. We retrospectively screened data of non-STEMI patients admitted to the coronary care unit of a tertiary center between March 2015 and March 2016. GRACE score was calculated and patients were classified into low (1 to 108), intermediate (109 to 140) and high risk (>140) groups according to GRACE categories. SYNTAX scores were also calculated. 201 patients (mean age: 63 ± 12 years, 53.7% female) were admitted with a diagnosis of non-STEMI. The mean GRACE score and SYNTAX score of study population were 105 ± 34.1 and 16.9 ± 12. Based on the GRACE score for in-hospital deaths, the SYNTAX score was 14.2 ± 10.1 in the low-risk group, 16.0 ± 13.4 in the intermediators group, and 24 ± 12.2 in high-risk group (ANOVA p<0.0001). Posthoc Tukey analysis showed that the high-risk group had a significantly higher SYNTAX score than the low-risk and intermediate risk groups (p<0.0001 vs p=0.003 respectively). There were significant positive correlations between the SYNTAX score and GRACE scores of the study population calculated at admission for in-hospital deaths (r=0.363, p<0.0001). GRACE score can predict complexity of CAD (high risk coronary anatomy). As we can decide to perform early invasive strategy according to GRACE score, we may consider detecting high risk complex coronary anatomy during coronary angiography. So, we may be ready to discuss with heart team about treatment strategy (ad hoc PCI, multivessel PCI or CABG) in patients with high GRACE score. Before giving ADP receptor antagonist, we may consider CABG requirement in these patient population.

Key Words: GRACE score; SYNTAX score; Risk evaluation; Coronary artery disease; Non-STEMI

A cute coronary syndromes (ACS) represent the most common cause of death in the western world (1). The term ACS defines a large spectrum of patients including unstable angina, myocardial infarction without ST segment elevation (non-STEMI) and myocardial infarction with ST segment elevation (STEMI) all of which have different mortality and morbidity risks, thus different treatment strategies are applied. Primary percutaneous coronary intervention (PCI) is the treatment of choice for STEMI with a Class I indication whereas for non-STEMI current cardiology guidelines recommend a risk based treatment approach so that time and use of certain pharmacological and interventional strategies are decided according to patient’s risk status (2-5). The most widely used risk scores are the ‘Thrombolysis in Myocardial Infarction (TIMI) and ‘Global Registry of Acute Coronary Events’ (GRACE) risk scores and their prognostic value has been validated in different clinical trials (6,7). GRACE score has been shown a better predictor of clinical outcome than the TIMI score (8,9). Both of these risk scores include only clinical variables whereas not only data derived from clinical characteristics but also anatomic extent and severity of the disease contributes significantly to the patient’s risk and has an important impact on treatment decision. 40% to 60% of STEMI patients have multi-vessel disease (10). The risk of mortality and reinfarction are much higher among patients with multi-vessel disease than single vessel disease (11). Although the risk is high in this group, no randomized data exist about the role of complete coronary revascularization in both NSTEMI and STEMI patients. In this setting, guidelines are also ambiguous and inconclusive (3,4).

The SYnergy between coronary intervention with TAXus and cardiac surgery (SYNTAX) I score is validated as a comprehensive tool for grading the complexity of Coronary Artery Disease (CAD) as well as discriminating low and high-risk patients for percutaneous or surgical intervention in patients with multi-vessel disease (12). Current guidelines recommend SYNTAX I score to identify the potential candidates for surgery among patients with ACS. Especially among those with non-STEMI before invasive imaging is of utmost importance as clopidogrel use prior to surgery is a major concern in this group.

This study is designed to assess the usefulness of GRACE risk score on admission in predicting high risk anatomy of non-STEMI patients defined by angiographic SYNTAX I score.

SUBJECTS AND METHODS

In this single center study, we retrospectively screened data of non-STEMI patients admitted to the coronary care unit of a tertiary center between March 2015 and March 2016. Records of patients with a diagnosis of non-STEMI were re-evaluated to confirm the diagnosis. Non-STEMI was defined as new onset or worsening chest pain occurring at rest or with minimal exertion with positive cardiac markers (troponin value above the 99th percentile) and without ST segment elevation (3-5). Patients who is not suitable coronary angiography during index admission (due to death, patient rejection, physician preference), patients with previous coronary artery bypass grafting (CABG) and PCI history, malignancy, valvular heart disease (especially severe aortic stenosis), hypertrophic cardiomyopathy, inflammatory disorders and conditions causing troponin elevation other than coronary artery disease were excluded. Clinical, biochemical and angiographic findings were obtained from hospital records. All electrocardiograms (ECG) were reevaluated to confirm the diagnosis.

GRACE score consisting of eight variables (age, heart rate on admission, systolic blood pressure (SBP) on admission, plasma creatinine, Killip class, ST-segment deviation, elevated troponins and cardiac arrest at admission) was calculated as described ranging from 0 to 372 (8). Patients were classified into low (1-108), intermediate (109-140) and high risk (>140) groups according to GRACE categories.

Coronary angiography and SYNTAX I score

In our institution, selective coronary angiograms are performed using standard projections, two for right coronary artery (RCA) (left anterior oblique-AP 30° and anteroposterior-AP Cranial 15° to 20°) and five for left anterior descending artery (LAD) (AP Caudal 15° to 20°, Left 40° and Caudal 20°, Left 40° and Cranial 20°, AP Cranial 40° and Left 40° and Caudal 20°). Coronary angiograms were evaluated by two senior invasive cardiologists who were used to SYNTAX I scoring algorithm and blinded to patient’s clinical data. SYNTAX I scores were calculated as described (12) and patients were also grouped as having 1-, 2- or 3-vessel disease. Stenosis >50% were considered as significant.

The study protocol was approved by the Istanbul University Institute of Cardiology Ethics Committee.

STATISTICAL METHOD

Continuous variables are presented as mean ± standard deviation and were compared using the Student’s t-test. Categorical variables are summarized as numbers and percentages and were compared by the Pearson’s Chi-square test. The associations between the SYNTAX I score and patient characteristics

| Triglyceride, mg/dL     | 167.4 ± 107.5|

BUN: Blood Urea Nitrogen; CAD: Coronary Artery Disease; CABG: Coronary Artery By-pass Grafting; Efr: Estimated Glomerular Filtration Rate; HDL: High Density Lipoprotein; LDL: Low Density Lipoprotein

RESULTS

During the study period, 201 patients (mean age: 63 years ± 12 years, 53.7% female) were admitted to our coronary unit with a diagnosis of non-STEMI. More than half of the patients had diabetes mellitus (63.7%), previous CAD history (74.6%) and familial history of CAD (72.1%). The mean GRACE score, SYNTAX I score and CRUSADE score of study population were 105 ± 34.1, 16.9 ± 12.1 and 27.7 ± 15.0 respectively. Clinical characteristics and laboratory values of the study population are presented in Table 1.

Based on the GRACE score for in-hospital deaths, 108 (53.7%) patients were included in the low-risk group, 44 (21.9%) in the intermediators group, and 49 (24.4%) in the high-risk group (141-372). The ratio of low risk to intermediate-high risk patients (according to GRACE score) in study population were nearly similar (53.7% and 46.3). The analysis of coronary angiography showed that the mean SYNTAX I score of the study population was 16.9 ± 12.1. Based on the GRACE score for in-hospital deaths, the SYNTAX I score was 14.2 ± 10.1 in the low-risk group, 16.0 ± 13.4 in the intermediators group, and 24 ± 12.2 in high-risk group (ANOVA, p<0.0001) (Figure 1).

Post-hoc Tukey analysis showed that the high-risk group had a significantly higher SYNTAX I score than the low-risk and intermediate risk groups (p<0.0001 vs p=0.003 respectively). There were significant positive correlations between the SYNTAX I score and GRACE scores of the study population calculated at admission for in-hospital deaths (r=0.363, p<0.0001) (Figure 2).

The GRACE score of the study population calculated at admission for in-hospital deaths showed good discriminatory capacity between the patients with and without a high-risk (>33) SYNTAX I score, with an area under the ROC curve of 0.644 (CI 0.567-0.721, p<0.0001) (Figure 3).

DISCUSSION

The GRACE scoring system is currently used for risk stratification of patients with non-STEMI. It is based on multivariable models that integrate elements from the medical history, physical examination, presence of cardiac arrest on admission, STT changes on admission ECG, and biochemical evidence of
myocyte necrosis (8). Given the wide spectrum of risk for death and recurrent events among patients with NSTE-ACS, the latest ESC guideline of 2015 recommends an early inva-sive strategy (<24 hours) in non-STEMI patients of high risk (GRACE score >140) (Class IIb) (5). Our study population was consisted of 46.3% intermediate-high risk patients according to GRACE score.

GRACE score alone is a clinical score. It identifies the high-risk patients that may benefit from early invasive strategy (8). Nevertheless, the prognosis of the patients cannot be considered independently of the extent and complexity of CAD. In this study, we used SYNTAX I score, a quantitative angiographic score, to determine the severity of atherosclerotic burden, as the latest ESC guideline recommends (5). The SYNTAX I score is widely accepted and its prognostic value has been demonstrated (12). SYNTAX I score ≥ 33 shows a highly complex CAD, and current European revascularization guidelines recommends surgical revascularization for subjects with a SYNTAX I score of ≥ 33 (class IA) (4,5). The mean SYNTAX I score of our study population was 16.9 ± 12.1.

The latest ESC guideline of 2015 also states to base the revascularization strategy (e.g. ad hoc culprit-lesion PCI, multivessel PCI, CABG) on the clinical status and comorbidities as well as the disease severity (including distribution, angiographic lesion characteristics, SYNTAX I score), according to the local Heart Team protocol (Class IC) (5). Our study revealed that, in patients with non-STEMI, the GRACE score has a positive predictive value for the presence of a greater extent and burden of CAD and most likely requiring CABG. The positive relationship between the GRACE and SYNTAX I scores may have some clinical implications. As we can determine the group of patients that benefit from early invasive strategy by calculating the GRACE score on admission, we can also predict the complexity of CAD before coronary angiography through this positive correlation between GRACE and SYNTAX I score. Predicting high risk coronary anatomy before coronary angiography is quite important because it affects the treatment modality (e.g. ad hoc culprit-lesion PCI, multivessel PCI, or CABG) and antiplatelet choice (to prevent CABG related major bleeding).

There are studies that investigate the role of GRACE score in the prediction of high-risk coronary anatomy in patients with NSTE-ACS in the literature. Kilickiran et al. demonstrated association between high risk coronary anatomy and GRACE score (13). In their study, patients with high risk coronary anatomy (based on SYNTAX I score ≥ 33) had higher GRACE score than low risk coronary anatomy (SYNTAX I score <33). Differently we used GRACE score to predict complexity of CAD in our study. Patients were divided into 3 groups (low, intermediate and high risk) according to GRACE score in our study and the SYNTAX I score was the highest in the high-risk population (GRACE score >140). So, we demonstrated that a clinical risk score can predict anatomic complexity. So, we may advice against giving ADP receptor antagonist (clopidogrel, ticagrelor) before coronary angiography to patients with non-STEMI, the GRACE score has a positive predictive value for the presence of a greater extent and burden of CAD and most likely requiring CABG. The positive relationship between the GRACE and SYNTAX I scores may have some clinical implications. As we can determine the group of patients that benefit from early invasive strategy by calculating the GRACE score on admission, we can also predict the complexity of CAD before coronary angiography through this positive correlation between GRACE and SYNTAX I score. Predicting high risk coronary anatomy before coronary angiography is quite important because it affects the treatment modality (e.g. ad hoc culprit-lesion PCI, multivessel PCI, or CABG) and antiplatelet choice (to prevent CABG related major bleeding).

There are studies that investigate the role of GRACE score in the prediction of high-risk coronary anatomy in patients with NSTE-ACS in the literature. Kilickiran et al. demonstrated association between high risk coronary anatomy and GRACE score (13). In their study, patients with high risk coronary anatomy (based on SYNTAX I score ≥ 33) had higher GRACE score than low risk coronary anatomy (SYNTAX I score <33). Differently we used GRACE score to predict complexity of CAD in our study. Patients were divided into 3 groups (low, intermediate and high risk) according to GRACE score in our study and the SYNTAX I score was the highest in the high-risk population (GRACE score >140). So, we demonstrated that a clinical risk score can predict anatomic complexity. So, we may advice against giving ADP receptor antagonist (clopidogrel, ticagrelor) before coronary angiography to consider CABG requirement according to our study results. But our study is small sample size, single center experience and retrospective in nature. We need large scale and prospective studies to be able to give such important recommendations.

CONCLUSION
In conclusion, GRACE score can predict complexity of CAD (high risk coronary anatomy). As we can decide to perform early invasive strategy according to GRACE score, we may consider detecting high risk complex coronary anatomy during coronary angiography. So, we may be ready to discuss with Heart team about treatment strategy (ad hoc PCI, multivessel PCI or CABG) in patients with high GRACE score. Before giving ADP receptor antagonist, we may consider CABG requirement in these patient population.
