We propose a design for the construction of a laboratory system based on present-day technology which reproduces and thereby simulates the quantum dynamics of the \(O(3)\) nonlinear sigma model. Apart from its relevance in condensed-matter theory, this strongly interacting quantum field theory serves as an important toy model for quantum chromo-dynamics (QCD) since it reproduces many crucial properties of QCD.

PACS numbers: 03.67.-a, 03.67.Lx, 11.10.Kk, 68.65.-k.

Introduction In many areas of physics, progress has been thwarted by our lack of understanding strongly interacting quantum systems with many degrees of freedom such as quantum field theories. Beyond perturbation theory with respect to some parameter or semiclassical models/methods, there are not many analytical tools available for the treatment of these systems. Numerical methods are hampered by the exponentially increasing amount of resources required for the simulation of quantum systems with many degrees of freedom in general. However, this obstacle applies to classical computers only – quantum computers will be able to simulate other quantum systems with polynomial effort. But as long as universal quantum computers of sufficient size (e.g., number of QuBits) are not available, one has to search for alternatives. One possibility is to design a special quantum system in the laboratory which reproduces the Hamiltonian of a particular quantum field theory of interest. This designed quantum system can then be regarded as a special quantum computer (instead of a universal one) which just performs the desired quantum simulation. In this Letter, we propose such a quantum simulator for the example of the \(O(3)\) nonlinear sigma model and demonstrate that it can be constructed using present-day technology.

The Model The 1+1 dimensional \(O(N)\) \(\sigma\)-model is described by the \(O(N)\) and Poincaré invariant action

\[
\mathcal{L} = \frac{\hbar}{2c} \partial_\nu \sigma \cdot \partial^\nu \sigma = \frac{\hbar}{2c} \left[ (\partial_\nu \sigma)^2 - c^2 (\partial_\sigma \sigma)^2 \right],
\]

(1)

with the internal vector \(\sigma = (\sigma_1, \sigma_2, \ldots, \sigma_N) \in \mathbb{R}^N\) reflecting the \(O(N)\)-symmetry. So far, this theory describes \(N\) independent free fields, but the constraint

\[
\sigma^2 = \sigma_1^2 + \sigma_2^2 + \cdots + \sigma_N^2 = \frac{N}{g^2},
\]

(2)

introduces an interaction corresponding to the coupling \(g > 0\). For vanishing coupling \(g \downarrow 0\), the curvature of the constraint sphere (\(\sigma^2 = N/g^2\)) vanishes and we reproduce (locally) an effectively free theory. For finite coupling \(g > 0\), we obtain a non-trivially interacting theory as long as \(N \geq 3\), i.e., in the non-Abelian case. The classical ground state \(\sigma = \text{const}\) is \(O(N)\)-degenerate, but quantum interaction lifts that degeneracy and gives the classical Goldstone modes a mass gap, see, e.g., [3].

Properties Apart from its relevance in condensed-matter theory (partly due to its relation to spin-systems such as anti-ferromagnets, see, e.g., [4]), it can be shown that the 1+1 dimensional \(O(N)\) \(\sigma\)-model reproduces many crucial properties of quantum chromo-dynamics (QCD) and hence serves as an important toy model, see, e.g., [5]. The \(\sigma\)-model is renormalizable (in 1+1 dimensions, cf. [5]) and its running coupling \(g(p^2)\) generates asymptotic freedom \(g^2(p^2) \gg \Lambda^2 \propto 1/\ln(p^2/\Lambda^2)\), cf. [3]. In analogy to QCD, the classical scale invariance \(x^\nu \rightarrow \Omega x^\nu\) is broken dynamically corresponding to the dimensional transmutation \(g \rightarrow \Lambda\). Furthermore, the \(\sigma\)-model generates non-vanishing vacuum condensates such as \(\langle \mathcal{L} \rangle \neq 0\) in the operator product expansion and reproduces the trace anomaly \(\langle T_{\mu \nu} \rangle \neq 0\) (see, e.g., [5]). It also serves as a toy model for the study of the low-energy theorems and sum rules (see, e.g., [5]). For \(N = 3\), the \(\sigma\)-model exhibits instants (mapping of \(S_2\) onto \(\mathbb{R}^2\), cf. [4, 5]). Furthermore, the model is exactly solvable in the large-\(N\) limit, where it corresponds to massive free fields with sub-leading (in 1+1 dimensions) and the \(U(1)\)-problem of QCD (see, e.g., [5]).

The Analogue In order to reproduce the quantum dynamics of the the 1+1 dimensional \(O(N)\) \(\sigma\)-model according to Eqs. (1) and (2), let us consider a large number of perfectly insulating thin hollow spheres with the radius \(\rho\) lined up at equal distances \(\Delta x\) with single electrons being captured by the polarizability (inducing a finite extraction energy) on each of the hollow spheres. These insulating spheres are surrounded by an arrangement of superconducting spheres (radius \(\alpha\)) and wires (radius \(\delta\)) as depicted in Fig. 1 which generate controlled interactions of the confined electrons via their image charges. The involved length scales including the typical wavelength of the excitations \(\lambda\), the distance of elements (lattice spacing) \(\Delta x\), the distance between the insulating and the conducting spheres \(\gamma\), the radii of the insulating and
conducting spheres $\rho$ and $\alpha$ and wires $\delta$ (cf. Fig. 1) are supposed to obey the following hierarchy

$$\lambda \gg \Delta x \gg \gamma \gg \rho, \alpha \gg \delta.$$  

(3)

where the first term under the root is the classical electron radius over the square of the fine structure constant. The value of the effective coupling can be tuned by varying the ratio $\gamma/\rho \gg 1$ and may well be of order one (see parameters below). Strictly speaking, the above equation determines the value of the running coupling $g_{\text{eff}}(p^2)$ at a length scale corresponding to the lattice spacing $\Delta x$ (lattice renormalization scheme). In complete analogy to $\Lambda_{\text{QCD}}$, the coupling $g_{\text{eff}}^2(p^2) \propto 1/\ln(p^2/\Lambda_{\text{QCD}}^2)$ determines the induced scale of dynamical symmetry breakdown $\Lambda_{\sigma}$ of the $\sigma$-model (dimensional transmutation). This important quantity sets all other length scales such as the mass gap (see, e.g., [1]) and must satisfy the condition $m_{\sigma} \Delta x \ll 1$. Finally, identifying (again for $N = 3$)

$$\sigma(x = i \Delta x) = \frac{\sqrt{3}}{g_{\text{eff}}} \frac{r_i}{\rho},$$  

(8)

the continuum limit ($\sum \Delta x \to \int dx$ for $\lambda \gg \Delta x$) of Eq. 4 generates the Lagrangian 11 of the $O(3)$ nonlinear sigma model with the constraint 2 being implemented by $r_i^2 = \rho^2$.

Disturbances Of course, for a realistic proposal, it is essential to estimate the impact of the contributions which have been omitted so far. The additional kinetic terms due to inductances $L$ of the wires are negligible $LI^2 \ll m_e^2$ provided that

$$4 \frac{\alpha}{\Delta x} \left( \frac{g_{\text{eff}}}{e_0} \right)^2 \ln \left( \frac{\Delta x}{\delta} \right) \ll 1$$  

(9)

holds, i.e., for a sufficiently large slow-down (as one would expect). For the same reason, the influence of the zero-point fluctuations of the electromagnetic field (inductance of free space) is negligible.

In contrast to sequential quantum algorithms, where errors may accumulate over many operations, the quantum simulation under consideration is basically a ground state problem and hence more similar to adiabatic quantum computing [10]. In this case, decoherence can be neglected as long as the interaction energies of the disturbances are much smaller than the energy gap between the ground state and the first excited state [10]. For the nonlinear $\sigma$-model, this gap is determined by the induced scale $\Lambda_{\sigma}$ (in analogy to QCD). Therefore, the energies of all perturbations (e.g., impurities in the material) must be much smaller than the gap of order $\hbar g_{\text{eff}} \Lambda_{\sigma}$. In particular, in order to see quantum behavior (where the Heisenberg uncertainty relation becomes important), the temperature must be small enough

$$k_B T \ll \hbar g_{\text{eff}} \Lambda_{\sigma}.$$  

(10)

Another issue concerns the spins of the electrons, which have been omitted so far. Fortunately, we may fix the electron spins by a small external magnetic field (see the
next paragraph) and the various spin-spin and especially spin-orbit coupling terms are negligible (in comparison to $\hbar c_{\text{eff}}\Lambda_\varphi$) for the parameters provided below.

**Phase Diagram** Before investigating the impact of an external magnetic field, let us turn to the phase diagram of the nonlinear $\sigma$-model in terms of the temperature $T$ and the chemical potential $\mu$. For low temperatures $k_B T \ll \hbar c_{\text{eff}}\Lambda_\varphi$ and small chemical potentials $\mu \ll \hbar c_{\text{eff}}\Lambda_\varphi$, we basically get the usual vacuum state. Note that the introduction of a chemical potential necessitates the definition of a particle number (which is a nontrivial issue in interacting theories). In the $\sigma$-model, this can be achieved by means of the Noether current corresponding to the global $O(3)$ invariance $j_\nu = \sigma \times \partial_\nu \sigma$ and the associated global charge along some internal axis $n$ with $n^2 = 1$:

$$Q = \frac{1}{c_{\text{eff}}} n \cdot \int dx \sigma \times \dot{\sigma}. \quad (11)$$

For the laboratory system, the Noether charge $Q$ is just the total (orbital) angular momentum in units of $\hbar$. Note that still many charges $Q \gg 1$ are required to generate one magnetic flux quantum (due to $c_0 \gg c_{\text{eff}}$).

In terms of the chemical potential defined with respect to this (dimensionless) Noether charge, the grandcanonical Hamiltonian $\hat{H}_{\text{gc}}$ reads

$$\hat{H}_{\text{gc}} = \hat{H}_0 + \mu_{\text{N}} N = \hat{H}_0 + \mu_Q \hat{Q}. \quad (12)$$

Translating this expression back to our laboratory system in Eq. (10), we observe that the chemical potential exactly corresponds to an external magnetic field $B$ inducing the additional term $\dot{r} \cdot A = \dot{r} \cdot (r \times B)/3 - B \cdot (\dot{r} \times r)/3$:

$$\mu_{\text{eff}} = \frac{e\hbar}{3m} B. \quad (13)$$

(The second-order term $e^2 A^2/m$ is three orders of magnitude smaller for the parameters given below and can be neglected.) When the effective chemical potential $\mu_{\text{eff}}$ exceeds the energy gap of order $\hbar c_{\text{eff}}\Lambda_\varphi$, the structure of the ground state changes and the above Noether current $\dot{J}_\mu$ acquires a non-vanishing expectation value (quantum phase transition, see, e.g., [13]). At the critical field $B_{\text{crit}} = O(m c_{\text{eff}}\Lambda_\varphi/e)$ where this quantum phase transition occurs, the energy of the electron spins is of the same order as the gap $\mu_s \cdot B = O(\hbar c_{\text{eff}}\Lambda_\varphi)$ and thus much bigger than the temperature. Hence one can fix the electron spins with much smaller external magnetic fields $B \ll B_{\text{crit}}$ without disturbing the vacuum state too much. On the other hand, it is also possible to explore the full phase diagram (e.g., cross the quantum phase transition, monitored by a SQUID) by increasing the external magnetic field — which is completely equivalent to changing the chemical potential (and hence the number of particles). For the set of parameters discussed below, the critical field $B_{\text{crit}}$ is of order milli-Tesla.

**Experimental Parameters** The aforementioned constraints, in particular Eqs. (13) and (14), provide the frame of a window of opportunity for the experimental realization of the proposed quantum simulator — which is (fortunately) open to present-day technology. Let us first explore the limit set by the ultra-low temperatures. For solid bodies of reasonable size, one can reach temperatures of order 10 $\mu$K by electron gas cooling via spin relaxation. If we choose our parameters according to $\delta = 100$ nm, $\rho = 400$ nm, $\alpha = 500$ nm, $\gamma = 2.5 \mu$m, and $\Delta x = 12.5 \mu$m, we obtain $g_{\text{eff}} = O(1)$, $c_{\text{eff}} \approx 10^5$m/s, $\Lambda_\varphi^{-1} \approx 125$ $\mu$m, and $\hbar c_{\text{eff}}\Lambda_\varphi$ corresponds to 600 $\mu$K, which satisfies all of the above assumptions reasonably well. Alternatively, we may start from the present state of nanotechnology which facilitates the production of nanowires with a radius of order nanometer. If we explore this limit and choose $\delta = 1$ nm, $\rho = 12$ nm, $\alpha = 5$ nm, $\gamma = 25$ nm, and $\Delta x = 125$ nm, we obtain a similar value for $g_{\text{eff}}$ and $c_{\text{eff}} \approx 10^5$ m/s, but now $\hbar c_{\text{eff}}\Lambda_\varphi$ corresponds to a temperature of order Kelvin. The range between $\mu$K and fractions of a Kelvin as well as between nanometers and micrometers provides a two or three orders of magnitude wide window of opportunity and the optimum experimental parameters are probably somewhere in the middle.

The thin superconducting wires can be switched on and off by local variations of the temperature (below and above the critical value). If the interaction $V(r_{i+1}, r_i)$ is switched off, the energy spectrum of the electrons is determined by the usual spherical harmonics

$$E_\ell = \frac{\hbar^2}{2m} \frac{\ell(\ell + 1)}{\rho^2}. \quad (14)$$

The energy gap between the s-state $\ell = 0$ and the p-state $\ell = 1$, i.e., without interaction $V(r_{i+1}, r_i)$, is one order of magnitude larger than with interaction $\hbar c_{\text{eff}}\Lambda_\varphi$. Consistently, the interaction potential $V(r_{i+1}, r_i)$ between the electrons on different spheres is of the same order of magnitude as the gap between the s-state $\ell = 0$ and the p-state $\ell = 1$ on a single sphere leading to strong entanglement of the ground state. If we want to switch on the interaction $V(r_{i+1}, r_i)$ adiabatically (e.g., via changing the temperature of the wires) satisfying the condition for the adiabatic theorem $|\langle \psi_0 | d\hat{H}(t)/dt |\psi_1 \rangle |/(\Delta E_{01})^2 \ll 1$ in order to stay in the ground state $|\psi_0 \rangle$, the typical adiabatic switching time should be longer than a few picoseconds. Finally, for the parameters discussed above, the various spin-spin and spin-orbit coupling energies are at least two orders of magnitude smaller than $\hbar c_{\text{eff}}\Lambda_\varphi$.

**Summary** As we have demonstrated above, it is possible to construct a quantum simulator for the $O(3)$ nonlinear $\sigma$-model with present-day technology. Such a restricted quantum computer would allow the comparison, for a controllable scenario, between perturbative and non-perturbative analytical methods (renormalization flow [8, 9], instantons [4], operator product ex-
pansion and vacuum condensates, low-energy theorems and sum rules, the $S$-matrix etc.) as well as numerical results on the one hand with real quantum simulations on the other hand. In contrast to most of the numerical simulations, for example, the proposed quantum simulator works in real (laboratory) time, i.e., it is not necessary to perform a Wick rotation to Euclidean time. This advantage facilitates the study of the evolution of excitations, for example collisions ($S$-matrix etc.).

Furthermore, the proposed set-up allows a direct access to the quantum state and hence an investigation of the strong entanglement (e.g., in the ground state or near the quantum phase transition). This could be done via state-selective radio/micro-wave spectroscopy of transitions from the levels in Eq. (11) to some higher-lying empty and isolated internal level (of the semi-conductor) with a sharp energy, for example (fluorescence measurement). Generating the radio/micro-waves via a circuit (wave-guide) facilitates the position control of the measurement (vicinity of the inductance loop). Furthermore, one may also switch off the wires (e.g., by locally increasing the temperature) before the measurement.

It is also possible to create particles (and their anti-particles), which can be used to study the $S$-matrix, for example, via the illumination with (left and right) circular polarized radio/micro-wave radiation, cf. Eq. (11) and the subsequent remarks. Another interesting point is the robustness or fragility of non-perturbative properties (such as the instanton density) with respect to a small coupling to external degrees of freedom.

Apart from above points of interest, the construction of such a restricted quantum computer, which is especially dedicated to the simulation of the $O(3)$ nonlinear $\sigma$-model, would be an interesting feasibility study for more general quantum simulators for a comparably well understood (yet nontrivial) system. Finally, experience shows that the availability of a new tool (such as the proposed quantum simulator) yielding new tests/results usually leads us to a new level of understanding in physics with possibly unexpected outcomes.

**Outlook** After having handled and understood the 1+1 dimensional situation, the extension to 2+1 dimensions should not be very problematic. The 2+1 dimensional $O(3)$ nonlinear $\sigma$-model loses some of the properties discussed above, but also acquires novel features, such as skyrmions which are described by the topological current $j^\mu = \varepsilon^{\mu\nu\rho} \sigma \cdot (\partial_\rho \sigma \times \partial_\nu \sigma)$. The inclusion of an explicit $O(3)$-symmetry breaking term $n \cdot \sigma$ should be easy in 1+1 and 2+1 dimensions. Note that we did not incorporate a topological (Chern-Simons type) $\theta$-term $L_\theta = \theta \varepsilon^{\mu\nu\rho} \sigma \cdot (\partial_\rho \sigma \times \partial_\nu \sigma)$ in our 1+1 dimensional scenario (in analogy to the $\theta$-term $G_{\mu\nu} G^{\mu\nu}$ in QCD), whose implementation is less straight-forward. Further interesting topics are the behavior of strongly interacting quantum field theories (such as QCD and the $\sigma$-model) during the cosmic expansion and the (long-range) entanglement of QCD vacuum state (which might be used as a tool for diagnosis and a resource).
