Already more than 40 years ago, it has been suggested that because of the enormous mass densities in the cores of neutron stars, the hadrons in the centers of neutron stars may undergo a phase transition to deconfined quark matter. In this picture, neutron stars could contain cores made of pure (up, down, strange) quark matter which are surrounded by a mixed phase of quarks and hadrons. More than that, because of the competition between the Coulomb and the surface energies associated with the positively charged regions of nuclear matter and negatively charged regions of quark matter, the mixed phase may develop geometrical structures, similarly to what is expected of the sub-nuclear liquid-gas phase transition. In this paper we restrict ourselves to considering the formation of rare phase blobs in the mixed quark-hadron phase. The influence of rare phase blobs on the thermal and transport properties of neutron star matter is investigated. The total specific heat, $c_V$, thermal conductivity, $\kappa$, and electron-blob Bremsstrahlung neutrino emissivities, $\epsilon_{\nu,\text{BR}}$, of quark-hybrid matter are computed and the results are compared with the associated thermal and transport properties of standard neutron star matter. Our results show that the contribution of rare phase blobs to the specific heat is negligibly small. This is different for the neutrino emissivity from electron-blob Bremsstrahlung scattering, which turns out to be of the same order of magnitude as the total contributions from other Bremsstrahlung processes for temperatures below about $10^8$ K.

I. INTRODUCTION

Already many decades ago, it has been suggested that, because of the extreme densities reached in the cores of neutron stars, neutrons and protons may transform to quark matter in the cores of such objects [1–6]. Quark matter could thus exist as a permanent component of matter in the ultra-dense centers of neutron stars (see [7–11] and references therein). If the dense interior of a neutron star is indeed converted to quark matter, it must be three-flavor quark matter since it has lower energy than two-flavor quark matter. And just as for the hyperon content of neutron stars, strangeness is not conserved on macroscopic time scales, which allows neutron stars to convert confined hadronic matter to three-flavor quark matter until equilibrium brings this process to a halt.

As first realized by Glendenning [12], the presence of quark matter enables the hadronic regions of the mixed phase to arrange to be more isospin symmetric than in the pure phase by transferring charge to the quark phase in equilibrium with it. The symmetry energy will be lowered thereby at only a small cost in rearranging the quark Fermi surfaces. The electrons play only a minor role when neutrality can be achieved among the baryon-charge carrying particles. The stellar implication of this charge rearrangement is that the mixed phase region of the star will have positively charged regions of nuclear matter and negatively charged regions of quark matter.

Because of the competition between the Coulomb and the surface energies associated with the positively charged regions of nuclear matter and negatively charged regions of quark matter, the mixed phase may develop geometrical structures (see Fig. 1), similarly as it is expected of the subnuclear liquid-gas phase transition [13–15]. This competition establishes the shapes, sizes, and spacings of the rare phase in the background of the other in order to minimize the lattice energy [7, 11, 12, 16].

The change in energy accompanied by developing such geometrical structures is likely to be very small in comparison with the volume energy [12, 17–19] and, thus, may not much affect the global properties of a neutron star. However, the geometrical structure of the mixed
phase may be very important for irregularities (glitches) in the timing structure of pulsar spin-down as well as for the thermal and transport properties of neutron stars [8, 12, 17].

To calculate the neutrino-pair bremsstrahlung rates and thermal properties, we follow the method described in [20] and [21], which is commonly used for the calculation of the neutrino emissivity and thermal conductivity in the crusts of neutron stars. These authors considered contributions from electron-phonon scattering and Bragg diffraction (the static-lattice contribution). Furthermore, multi-phonon processes and electron band structure effects are incorporated to obtain more realistic scattering rates and a better connection between the solid and the liquid gas phase. Instead of adopting the analytic fits provided in [20] and [21], here we re-calculate the scattering rates from phonon sums using the method of [22]. There are two main reasons for this. The first being that, for the crust, the total ion charge is balanced by the total electron charge. This will be different for the mixed quark-hadron phase in the core of a neutron star, since electric charge neutrality is established between the electric charges of the rare phase, the dominant phase, since electric charge neutrality is established between the mixed quark-hadron phase in the core of a neutron star, the total electron charge. This will be different for the provided in [20] and [21], here we re-calculate the scattering rates and a better connection between the solid and the liquid gas phase. Instead of adopting the analytic fits provided in [20] and [21], here we re-calculate the scattering rates from phonon sums using the method of [22]. There are two main reasons for this. The first being that, for the crust, the total ion charge is balanced by the total electron charge. This will be different for the mixed quark-hadron phase in the core of a neutron star, since electric charge neutrality is established between the electric charges of the rare phase, the dominant phase, and the leptons which are present in both the rare and the dominant phase. The simple relation $n_e = Z n_i$ between electron density and ion density, used to derive the crustal fit formula in [20, 21], can therefore not be used to study the quark-hadron Coulomb lattice structure in the core of a neutron star. The second reason concerns the electric charge numbers themselves. For mixed phase blobs, they can easily exceed $Z \sim 10^3$, as will be shown in § II C. Charge numbers that high are obviously not reached in the crustal regimes of neutron stars [20], where there is usually no need to consider atomic nuclei with charges much larger than $Z > 56$.

The paper is organized as follows. In Section II, we briefly discuss the modeling of the mixed quark-hadron phase in the cores of neutron stars and the equations of state of confined hadronic and quark matter used in this work. In Section III, we summarize the formalism for calculating the neutrino-pair Bremsstrahlung emissivity and the thermal conductivity of rare phase blobs immersed in hadronic matter. The results are presented in Section IV.

II. MODELING OF THE MIXED QUARK-HADRON PHASE IN NEUTRON STARS

A. Hadronic matter

To compute the particle compositions of the cores of standard neutron stars, that is, neutron stars without deconfined quark degrees of freedom, we choose a relativistic lagrangian of the following type [8, 9],

$$\mathcal{L} = \sum_B \bar{\psi}_B [\gamma_\mu (i \slashed{\partial} - g_\omega \omega^\mu - g_\rho \slashed{\rho} \cdot \vec{\rho}_\mu) - (m_N - g_\sigma \sigma)] \psi_B + \frac{1}{2} (\partial_\mu \sigma \partial^\mu \sigma - m_\sigma^2 \sigma^2)$$

$$- \frac{1}{3} b_\rho m_N (g_\sigma \sigma)^3 - \frac{1}{4} c_\sigma (g_\sigma \sigma)^4 - \frac{1}{4} \omega^\mu \omega^\nu$$

$$+ \frac{1}{2} m_\omega^2 \omega_\mu \omega^\mu + \frac{1}{2} m_\rho^2 \vec{\rho}_\mu \cdot \vec{\rho}^\mu$$

$$- \frac{1}{4} \vec{\rho}^\mu \vec{\rho}_\nu \vec{\rho}^{\mu\nu} + \sum_{\lambda = e^- \mu^-} \tilde{\psi}_\lambda (i \gamma_\mu \partial^\mu - m_\lambda) \psi_\lambda,$$  (1)

where the sum over $B$ sums the baryon species listed in Table I. The sum over $\lambda$ accounts for the presence of relativistic electrons and muons in neutron star matter. Their masses are $m_e = 0.511$ MeV and $m_\mu = 105$ MeV. The quantities $g_\rho$, $g_\sigma$, and $g_\omega$ are meson-baryon coupling constants of $\sigma$, $\omega^\mu$, and $\rho^\mu$ mesons. Non-linear $\sigma$-meson self-interactions are taken into account in Eq. (1) via the terms proportional to $b_\rho$ and $c_\sigma$. The quantities $\vec{\tau}$ and $\gamma_\mu$ denote isospin vectors and Dirac matrices, respectively, and $\partial^\mu \equiv \partial / \partial x^\mu$ [7, 9]. We have solved the equations of motion for the baryon and meson fields, which follow

**TABLE I.** Masses $m_B$, electric charges $Q_B$, spin $J_B$, and third component of isospin $I_3^B$ of the baryons $B$ included in the lagrangian of Eq. (1) [8, 9].

| $B$ | Symbol | $m_B$ (MeV) | $Q_B$ | $J_B$ | $I_3^B$ |
|-----|--------|-------------|-------|-------|--------|
| $n$ | $\bar{n}$ | 939 | 0 | 1/2 | $-1/2$ |
| $p$ | $\bar{p}$ | 938 | 1 | 1/2 | 1/2 |
| $\Lambda$ | $\Lambda$ | 1115 | 0 | 0 | 0 |
| $\Sigma^+$ | $\Sigma^+$ | 1190 | 1 | 1 | 1 |
| $\Sigma^0$ | $\Sigma^0$ | 1190 | 0 | 1 | 0 |
| $\Sigma^-$ | $\Sigma^-$ | 1190 | -1 | 1 | -1 |
| $\Xi^0$ | $\Xi^0$ | 1315 | 0 | 1/2 | 0 |
| $\Xi^-$ | $\Xi^-$ | 1315 | -1 | 1/2 | -1 |
whose total number density is given by the baryon number and the electric charge of particles is necessary. The latter are given by the edge of two independent chemical potentials, which simplifies the mathematical analysis, since only knowledge of two independent chemical potentials, \( \mu_n \) and \( \mu_e \), is necessary. The latter are given by

\[
\mu_i = B_i \mu_n - Q_i \mu_e, \tag{2}
\]

with \( \mu_n \) and \( \mu_e \) are the chemical potentials of neutrons and electrons. The quantities \( B_i \) and \( Q_i \) stand for the baryon number and the electric charge of particles (mesons and baryons) of type \( i \). Equation (2) greatly simplifies the mathematical analysis, since only knowledge of two independent chemical potentials, \( \mu_n \) and \( \mu_e \), is necessary. The latter are given by

\[
\mu_B = g_\omega \omega + g_\rho \rho_0 I_B^3 + \sqrt{k_B^2 + m_B^2},
\mu_\lambda = \sqrt{k_\lambda^2 + m_\lambda^2}, \tag{3}
\]

where \( m_B^2 = m_B - g_\sigma \sigma \) denote the effective medium-modified baryon masses, \( k_B \) and \( k_\lambda \) are the Fermi momenta of baryons and leptons, respectively, and \( I_B^3 \) is the third component of the isospin vector of a baryon of type \( B \). Finally, aside from chemical equilibrium, the condition of electric charge neutrality is also of critical importance for the composition of neutron star matter. It is given by

\[
\sum_B Q_i (2J_B + 1) \frac{k_B^3}{6\pi^2} - \sum_\lambda \frac{k_\lambda^3}{3\pi^2} = 0. \tag{4}
\]

Figure 2 shows the baryon-lepton compositions of neutron star matter computed from Eq. (1) for the relativistic mean-field approximation. The quantity \( \rho_i \) in Fig. 2 stands for the individual number densities of baryons,

\[
\rho_B = (2J_B + 1) \frac{k_B^3}{3\pi^2}, \tag{5}
\]

whose total number density is given by

\[
\rho_b \equiv \sum_B \rho_B. \tag{6}
\]

The individual number densities of electrons and muons \( i = e^-, \mu^- \) are given by

\[
\rho_i = 2k_i^3/3\pi^3. \tag{7}
\]

The total energy density and pressure of the matter, shown in Fig. 2, follow from

\[
\epsilon_H = \frac{1}{3} b m_N (g_\sigma \sigma)^3 + \frac{1}{4} c (g_\sigma \bar{\sigma})^4 + \frac{1}{2} (m_\sigma \bar{\sigma})^2
+ \frac{1}{2} (m_\sigma \bar{\sigma})^2 + \frac{1}{2} (m_\rho \bar{\rho})^2
+ \sum_B \frac{1}{\pi^2} \int_0^{k_B} k^2 dk \sqrt{k^2 + m_B^2}
+ \sum_\lambda \frac{1}{\pi^2} \int_0^{k_\lambda} k^2 dk \sqrt{k^2 + m_\lambda^2}, \tag{8}
\]

and

\[
\rho_H = -\frac{1}{3} b m_N (g_\sigma \bar{\sigma})^3 - \frac{1}{4} c (g_\sigma \bar{\sigma})^4 - \frac{1}{2} (m_\sigma \bar{\sigma})^2
+ \frac{1}{2} (m_\sigma \bar{\sigma})^2 + \frac{1}{2} (m_\rho \bar{\rho})^2
+ \sum_B \frac{1}{\pi^2} \int_0^{k_B} k^2 dk \sqrt{k^2 + m_B^2}
+ \sum_\lambda \frac{1}{\pi^2} \int_0^{k_\lambda} k^2 dk \sqrt{k^2 + m_\lambda^2}. \tag{9}
\]
To model quark matter, we use the MIT bag model. Up \((u)\) and down \((d)\) quarks are treated as massless particles while the strange quark \((s)\) mass is assigned a value of \(m_s = 200\) MeV. First-order perturbative corrections in the strong interaction coupling constant \(\alpha\) are taken into account \([10, 26–28]\). The Landau potentials of up and down quarks are then given by

\[
\Omega_u = -\frac{\mu_u^4}{4\pi^2} \left(1 - \frac{2\alpha}{\pi}\right),
\]

\[
\Omega_d = -\frac{\mu_d^4}{4\pi^2} \left(1 - \frac{2\alpha}{\pi}\right),
\]

while for strange quarks we have

\[
\Omega_s = -\frac{1}{4\pi^2} \left\{\mu_s \sqrt{\mu_s^2 - m_s^2} (\mu_s^2 - \frac{5}{2}m_s^2)
\right.
\]

\[
+ \frac{3}{2} m_s^2 f(\mu_s, m_s)
\]

\[
- \frac{2\alpha}{\pi} \left[3 \left(\mu_s \sqrt{\mu_s^2 - m_s^2} - m_s^2 f(\mu_s, m_s)\right)^2
\right.
\]

\[
- 2 (\mu_s^2 - m_s^2)^2 + 3 m_s^4 \ln \frac{m_s}{\mu_s}
\]

\[
+ 6 \ln \frac{\sigma}{\mu_s} \left(\mu_s m_s^2 \sqrt{\mu_s^2 - m_s^2} - m_s^4 f(\mu_s, m_s)\right)\right\} ,
\]

where \(f(\mu, m) \equiv \text{ln}(\mu + \sqrt{\mu^2 - m^2})/m\), and \(\sigma\) is a renormalization constant whose value is of the order of the chemical potentials \([28]\). In this article we take \(\sigma = 300\) MeV. The Landau potentials of electrons and muons are given by

\[
\Omega_e = -\frac{\mu_e^4}{12\pi^2} ,
\]

\[
\Omega_\mu = -\frac{1}{4\pi^2} \left(\mu_\mu \sqrt{\mu_\mu^2 - m_\mu^2} \left(\mu_\mu^2 \frac{5}{2}m_\mu^2\right)
\right.
\]

\[
+ \frac{3}{2} m_\mu^4 \ln \frac{\mu_\mu + \sqrt{\mu_\mu^2 + m_\mu^2}}{m_\mu}\right\} .
\]

The condition of chemical equilibrium leads to

\[
\mu_d = \mu_s = \mu_u + \mu_e = \mu_u + \mu_\mu .
\]

The partial baryon number densities of the particles is obtained from \((i = u, d, s, e^-, \mu^-)\)

\[
\rho_i = -\partial \Omega_i / \partial \mu_i ,
\]

and the total energy density and pressure of quark matter follows from

\[
\epsilon_Q = \sum_i (\Omega_i + \mu_i \rho_i) + B ,
\]

and

\[
\rho_Q = -B - \sum_i \Omega_i ,
\]

where \(B\) denotes the bag constant. For \(\alpha, m_s \to 0\) one recovers from Eqs. (17) and (18) the standard equation of state of a massless relativistic quark gas, \(P = (e - 4B)/3\).
values of the strong interaction coupling constant \( \alpha \gtrsim 0.25 \) electrons disappear from the matter and positrons tend to emerge in the mixed phase. We therefore consider only \( \alpha \lesssim 0.2 \).

In Figure 5 we show the masses of neutron stars, whose compositions are given in Figs. 3 and 4. The underlying equations of state are given in Eqs. (8), (9), (17) and (18), and the parameter sets are listed in Table III. The Baym-Pethick-Sutherland (BPS) model for the equation of state has been used to model the crusts of these neutron stars [29]. The maximum masses of the quark-hybrid stars computed for HV1 and HV2 are 1.47 \( M_\odot \) and 1.61 \( M_\odot \), respectively. For G300I and G300II we obtain maximum masses of 1.58 \( M_\odot \) and 1.69 \( M_\odot \), respectively. These values are too low to accommodate the recently discovered heavy pulsar PSR J1614–2230, whose mass is \( M = 1.97 \pm 0.04 M_\odot \) [30]. One possible explanation could be that the high rotation rate of this neutron star prevents the hadrons in the core of this neutron star from transforming to quark-hadron matter.

This neutron star could thus be made entirely of confined hadronic matter, whose equation of state is stiffer than the equation of state of quark-hybrid matter, supporting high-mass neutron stars. As found in [31], massive (~ 2 \( M_\odot \)) non-rotating neutron stars with extended regions of deconfined quarks and hadrons are comfortably obtained in the framework of the nonlocal SU(3) Nambu-Jona Lasinio model. This model is not considered in this paper, however, since our results are largely independent of the particular microscopic many-body model chosen to determine the equation of state of bulk quark-hadron matter.

As pointed out in [7, 12] the isospin restoring force can exploit degrees of freedom made available by relaxing the requirement of strict local charge neutrality to neutrality on larger scales and form a positively charged hadronic matter region with lower isospin asymmetry energy and a negatively charged quark matter region. The competition between the Coulomb interaction and the surface energy will result in a crystalline lattice of the rare phase in the dominant phase. The size and spacing of the crystalline lattice is determined by minimizing the total energy. The situation is similar to the atomic nuclei immersed in a relativistic electron gas in the crusts of neutron stars.

Depending on density, the embedding of the rare phase in the dominant phase can lead to different geometric structures, including spherical blobs, rods and slabs. In what follows, we restrict ourselves to the discussion of spherical blobs. For an electrically charge neutral Wigner-Seitz cell, with spherical blob of radius \( r_b \), the
Coulomb and surface energy density can be expressed as

\[ \epsilon_C = 2\pi\alpha_e [q_H(\chi) - q_Q(\chi)]^2 r_b^2 \chi f_3(x), \quad (22) \]

\[ \epsilon_S = 3\chi \sigma(\chi)/r_b, \quad (23) \]

where \( \alpha_e = 1/137 \) is the fine structure constant, \( x = \min(\chi, 1 - \chi) \) is the volume fraction of rare phase, \( f_3(x) = (x - 3x^{1/3} + 2)/5 \) is the function \( f_d(x) \) for \( d = 3 \), which arises from calculating the electrostatic binding energy of the cell \([7]\). Due to theoretical difficulties it is very hard to estimate the surface tension \( \sigma \). Here we follow \([7]\) and take a gross approximation expression for the surface tension first proposed by Gibbs \([32]\), where the surface energy is proportional to the difference of the energy densities of the two phases,

\[ \sigma(\chi) = \eta L [\epsilon_Q(\chi) - \epsilon_H(\chi)], \quad (24) \]

where \( \eta \) should be on the order of \( \eta \sim \mathcal{O}(1) \), and we take \( L = 1 \) fm. Three different values for the constant \( \eta \) (i.e., 0.5, 1, and 2) are used in our calculations to investigate the effects caused by uncertainties in the value of the surface tension.

Since \( \epsilon_C \propto r_b^2 \) and \( \epsilon_S \propto r_b^{-1} \), it is possible to minimizing the total energy \( \epsilon_C + \epsilon_S \) at fixed \( \chi \) which leads to an equilibrium radius of the rare phase of blobs inside of Wigner-Seitz cells,

\[ r_b = \left( \frac{3\sigma(\chi)}{4\pi\alpha_e [q_H(\chi) - q_Q(\chi)]^2 f_3(x)} \right). \quad (25) \]

The radii of spherical blobs of the rare phase, \( r_b \), and the radii of Wigner-Seitz cells, \( a \), as a function of quark volume fraction, \( \chi \), for different surface tensions, \( \eta \), and parameter sets (Table III) of the hadronic lagrangian.

The values of \( Z, A \) and \( Z_{\text{eff}} \) as a function of the quark volume fraction \( \chi \) are shown in Fig. 6. The radii of spherical blobs is in the range of 10 to 30 fm. To compare our situation to the crust we also calculate the charge \( Z \) and mass number \( A = m_b/m_u \) of the rare phase blobs, with \( m_b \) being the blob mass. In addition we define an effective electric charge number given by

\[ Z_{\text{eff}} = \frac{n_e}{n_b}, \quad (26) \]

where \( n_b \) is the number density of the spherical blobs. As can be seen, the charge and mass numbers are typically one to two orders of magnitude greater than that of the heaviest stable nuclei, but due to a dramatic drop in electron density the value of \( Z_{\text{eff}} \) can fall near and below \( Z_{\text{eff}} \sim 10 \) as \( \chi \to 1 \). The discontinuities of the curves in Figure 7 at \( \chi = 0.5 \) are due to the differences in the hadronic and quark phase densities at \( \chi = 0.5 \). It is also worth noting that near the edges of the mixed phase region (\( \chi \to 0, 1 \)) the volume density of blobs \( n_b = 3x/(4\pi r_b^3) \) vanishes, but since \( f_3(0) = 2/5 \), the blob radius \( r_b \) approaches a constant \( r_b \to r_b(x = 0) \). Therefore \( Z_{\text{eff}} = n_e/n_b \) diverges at the edges of the mixed phase region.

cal blobs of rare phase as a function of quark volume fraction, \( \chi \).

FIG. 8. (Color online) Electric charge number, \( Z \), of spherical
blobs of rare phase as a function of quark volume fraction, \( \chi \).

III. THERMAL AND TRANSPORT
PROPERTIES OF QUARK-HADRON PHASE

Next, we turn our interest to the calculation of the
thermal and transport properties of a mixed phase of
quarks and hadrons. Knowledge of these properties is of
key importance in order to carry out thermal evolution
simulations of neutron stars with hypothetical quark-
hadron cores and to determine possible astrophysical sig-
natures hinting at the existence of such matter inside of
neutron stars. Our focus here is on exploring the impact
of rare phase blobs on the following properties: specific
heat \( c_V \), neutrino emissivity \( \epsilon_\nu \), and thermal conductivity \( \kappa \).

From the outset, one might expect that, because of the
geometric structures in the mixed phase, new degrees of
freedom are introduced to the system, which may store
additional thermal energy and hence would increase the
specific heat. Due to the scattering of degenerate elec-
trons and rare phase blobs in the mixed phase, there
will also be an additional contribution to the neutrino
Bremsstrahlung and an additional microscopic entropy
production rate which reduces the total thermal conduc-
tivity.

A. Basic physical quantities

We first introduce some of the basic physical quanti-
ties and functions used in the calculation of the thermal
and transport properties of the quark-hadron phase. The
state of the mixed phase with rare phase blobs is deter-
mined by the ion-coupling parameter [20],

\[
\Gamma = \frac{Z^2 e^2}{ak_B T},
\] (27)
where \( a = (3/(4\pi n_b))^{1/3} \) is the Wigner-Seitz cell radius, which is related to the spherical blob radius by \( x = (r_b/a)^3 \). The quantity \( \Gamma_m = 172 \) corresponds to the melting point below which a classical one-component Coulomb crystal (\( \Gamma < \Gamma_m \)) becomes a Coulomb liquid (\( 1 < \Gamma < \Gamma_m \)) [33]. Therefore the melting temperature is given by \( T_m = Z^2 e^2/(ak_B \Gamma_m) \). Another important quantity is the plasma temperature,

\[
T_p = \frac{\hbar \omega_p}{k_B}, \tag{28}
\]

where \( \omega_p = (4\pi Z^2 e^2 n_b/m_b)^{1/2} \) denotes the plasma frequency of the spherical blobs, with \( m_b \) the mass of the spherical blobs. For later, it is convenient to use the temperature in units of the plasma temperature, \( t_p = T/T_p \). For temperatures \( t_p \lesssim 1/8 \) the vibrations of a Coulomb crystal must be treated quantum mechanically [20].

Besides the Coulomb interaction, there are three effects which must be taken into account to describe the interaction between electrons and rare phase blobs. These are the screening of electrons, the shape of the blob and the effect of thermal vibrations. The Fourier transform of the effective electron-blob interaction is given by [20]

\[
V(q) = \frac{4\pi e \rho_Z F(q)}{q^2 \epsilon(q)} e^{-W(q)}, \tag{29}
\]

where \( \rho_Z \) is the blob charge per unit volume \( \rho_Z = \chi q \) for \( \chi < 1/2 \), and \( \rho_Z = (1 - \chi) q m_H \) for \( \chi > 1/2 \). The quantity \( \epsilon(q) \) in Eq. (29) is the static longitudinal dielectric factor adopted from [34] and \( F(q) \) is the form factor of a blob. For simplicity, we assume a uniform distribution of the electric charge in the rare phase and use \( F(q) = (3/(q r)^3) [\sin(q r) - q r \cos(q r)] \) [20].

Thermal vibrations of rare phase blobs are taken into account via the Debye-Waller factor,

\[
W(q) = \frac{\hbar^2}{4 m_b} \left( \coth(\hbar \omega_s/(2k_B T)) \right) \left( \frac{\omega_s}{\omega_p} \right)^{2}, \tag{30}
\]

where \( \omega_s \) is the phonon frequency. Here \( \langle \ldots \rangle_{ph} \) denotes the average over the phonon wave vectors and polarizations.

Throughout this article, we use the method of [22] to compute phonon sums. It is assumed that there are three polarizations of phonons: two transverse modes with linear dispersion relations \( \omega_k^{(t, \pm)} = a_i k \) \( (i = 1, 2) \), and one longitudinal mode which is determined through Kohn's sum rule \( \omega_L^2 + \omega_{T,1}^2 + \omega_{T,2}^2 = \omega_p^2 \), where \( \omega_p \) denotes the plasma frequency. The two parameters \( a_1 \) and \( a_2 \) are determined by fitting the frequency moments \( u_n \equiv \langle \omega^n \rangle_{ph} \) of the specified lattice type. For a bcc lattice, the frequency moments \( u_{-1} = 2.7990 \) and \( u_{-2} = 12.998 \) are well known [35], and are used to obtain \( a_1 = 0.58273 \), \( a_2 = 0.32296 \). These parameters also produce first and fourth moments: \( \mu_1 = 0.51106 \), \( \mu_4 = 0.201946 \) which are quite close to the exact values of \( \mu_1 = 0.51139 \) and \( \mu_4 = 0.203076 \) [35]. In the special case of the Debye-Waller factor, the phonon sum can be fitted very well by the following analytic formula [36],

\[
W(q) = \frac{\alpha_0}{2} \left( \frac{q}{2k_F} \right)^2 \left( \frac{1}{2} u_{-1} e^{-9.11 q} + t_p u_{-2} \right), \tag{31}
\]

where \( k_F \) is electron Fermi wave number and \( \alpha_0 \) is a constant given in [20]. The latter can be rewritten as

\[
\hat{a} = \frac{\alpha_0}{2} = \frac{3^{2/3} \pi^{1/6} \hbar^{1/2}}{\alpha e^2 c^{1/2}} Z m_b^{1/2} n_b^{1/2}. \tag{32}
\]

With the help of Eq. (32) the Debye-Waller factor can be written as \( W(y^2 \hat{a}, t_p) \), where \( y = q/(2 k_F) \).

**B. Neutrino Bremsstrahlung emissivity**

Next we turn to the calculation of electrons off the rare phase blobs (that is, electron-blob Bremsstrahlung), which leads to the generation of neutrino–anti-neutrino pairs according to the reaction \( e^- + (Z, A) \to e^- + (Z, A) + \nu + \bar{\nu} \). The associated neutrino Bremsstrahlung emissivity can be written as [37]

\[
\epsilon_\nu = \frac{8\pi G_F^2 Z^2 e^4 C^2}{567 \hbar^2 c^8} (k_B T)^6 n_b L, \tag{33}
\]

where \( n_b \) is the number density of the rare phase blobs and \( G_F = 1.346 \times 10^{-49} \text{ erg cm}^3 \) is the Fermi weak coupling constant, \( C^2 \approx 1.675 \) [20], and \( L \) is a dimensionless function given by

\[
L = L_{ph} + L_{sl} \quad \text{or} \quad L = L_{liq}, \tag{34}
\]

where \( L_{ph} \) accounts for the scattering of electrons off the phonons of the Coulomb crystal of rare phase blobs, \( L_{sl} \) accounts for Bragg scattering between electrons and the static Coulomb crystal lattice, and \( L_{liq} \) is for the liquid phase. In the liquid phase the general expression is obtained through a variational approach in Born approximation [37—39],

\[
L_{liq} = \int_0^1 dy \frac{S(q)|F(q)|^2}{y|\epsilon(q)|^2} \left( 1 + \frac{2y^2}{1 - y^2} \ln y \right), \tag{35}
\]

where \( y = q/(2 k_F) \). We follow [20] for the choice of the ion-ion structure factor \( S(q) \), which was fitted in [40, 41].

For a solid phase the phonon contribution is mainly given by the screening of electrons, the shape of the blob and the effective static structure factor \( S_{eff} \) is obtained from the summation of

\[
L_{ph} = \int_{y_0}^1 dy \frac{S_{eff}(y^2 \hat{a}, t_p)|F(y)|^2}{y|\epsilon(y)|^2} \left( 1 + \frac{2y^2}{1 - y^2} \ln y \right), \tag{36}
\]
multi-phonon diagrams [20, 42]. For the parameter sets chosen in this calculation we always have \(Z_{\text{eff}} \gg 1/4\) so that \(y_0 < 1\). \(S_{\text{eff}}\) can be written in terms of a rapidly decreasing integral [20],

\[
S_{\text{eff}}(y^2 \tilde{a}, t_p) = 189 \left( \frac{2}{\pi} \right)^5 e^{-2W(y^2 \tilde{a}, t_p)}
\times \int_0^\infty d\xi \frac{1 - 40\xi^2 + 80\xi^4}{(1 + 4\xi^2)^5 \cosh^2(\pi \xi)}
\times \left( e^{\Phi(\xi, y^2 \tilde{a}, t_p)} - 1 \right), \tag{37}
\]

where

\[
\Phi(\xi, x, t_p) \equiv x \left( \frac{\cos \left( \frac{\xi x}{\omega} \right)}{\omega \sinh \left( \frac{\omega x}{2 t_p} \right)} \right)_{\text{ph}},
\]

with \(\omega \equiv \omega_0/\omega_p\) denoting the phonon frequency in units of the plasma frequency. Similarly to the analysis in [20], there exist approximate expressions for \(S_{\text{eff}}\) for the limiting cases where \(t_p \ll 1\) and \(t_p \gg 1\), which is discussed next. For this purpose, we write the \(x\)-independent part of \(\Phi(\xi, x, t_p)/t_p\) as

\[
\psi(\xi, t_p) \equiv \frac{1}{t_p} \left( \frac{\cos \left( \frac{\xi x}{\omega} \right)}{\omega \sinh \left( \frac{\omega x}{2 t_p} \right)} \right)_{\text{ph}}.
\]

For \(t_p \ll 1\) and \(t_p \gg 1\), \(\psi(\xi, t_p)\) can be replaced by

\[
\psi(\xi, t_p) \to \begin{cases}
\psi(0, t_p) \psi(\xi), & t_p \ll 1, \\
\psi(0, t_p) - \tilde{F}(t_p)x^2, & t_p \gg 1,
\end{cases}
\]

where

\[
\tilde{\psi}(\xi) \equiv \lim_{t_p \to 0} \frac{\psi(\xi, t_p)}{\psi(0, t_p)}
\]

is computed numerically. It is a rapidly decaying function of \(\xi\) and is negligibly small for \(\xi \gg 2\). The function \(\tilde{F}(t_p) \equiv \langle \omega/[2t_p^2 \sinh(\omega/2 t_p)] \rangle_{\text{ph}}\) is computed numerically for \(1 \leq t_p < 10^2\). Asymptotically, \(\tilde{F}(t_p)\) has the form

\[
\tilde{F}(t_p) = \left\{ \begin{array}{ll}
96 \left( \frac{1}{a^1} + \frac{1}{a^2} \right) t_p, & t_p \lesssim 1, \\
\frac{1}{t_p^1}, & t_p \gtrsim 1.
\end{array} \right.
\]

The function

\[
\psi(0, t_p) = \left( \frac{1}{\omega t_p \sinh \left( \frac{\omega x}{2 t_p} \right)} \right)_{\text{ph}},
\]

can be calculated numerically for a broad range of \(t_p\) values, and can be shown to behave as

\[
\psi(0, t_p) = \begin{cases}
2u_{-2} - \frac{1}{12}, & t_p \gtrsim 1, \\
\alpha^2 \left( \frac{1}{a^1} + \frac{1}{a^2} \right) t_p, & t_p \lesssim 10^{-3}.
\end{cases}
\]

With the aid of Eqs. (39) to (44), we can now derive low and high temperature limits of the effective structure factor \(S_{\text{eff}}\) of Eq. (37). For \(t_p \ll 1\) one obtains

\[
S_{\text{eff}}(x, t_p) = 189 \left( \frac{2}{\pi} \right)^5 e^{-2W(x, t_p)} G_{\text{eff}}(x t_p \psi(0, t_p)),
\]

while for \(t_p \gg 1\)

\[
S_{\text{eff}}(x, t_p) = 189 \left( \frac{2}{\pi} \right)^5 e^{-2W(x, t_p) + x t_p \psi(x, t_p)} \times H_{\text{eff}}(x t_p F(t_p)) - e^{-2W(x, t_p)}. \tag{46}
\]

Here we have defined

\[
G_{\text{eff}}(a) \equiv \int_0^\infty \frac{1 - 40\xi^2 + 80\xi^4}{(1 + 4\xi^2)^5 \cosh^2(\pi \xi)} \times \left( e^{a \tilde{\psi}(\xi)} - 1 \right),
\]

which obeys

\[
G_{\text{eff}}(a) \approx \begin{cases}
eq 41 \times 10^{-5}, & a \lesssim 10^2, \\
181 \times 10^{-5}, & a \lesssim 0.1.
\end{cases}
\]

For \(0.1 \leq a \leq 10^2\) the value of \(G_{\text{eff}}\) is obtained numerically. The quantity \(H_{\text{eff}}\) in Eq. (46) is defined as

\[
H_{\text{eff}}(a) \equiv \int_0^\infty \frac{1 - 40\xi^2 + 80\xi^4}{(1 + 4\xi^2)^5 \cosh^2(\pi \xi)} e^{-a \xi^2}.
\]

Asymptotically, \(H_{\text{eff}}\) behaves as

\[
H_{\text{eff}}(a) \approx \begin{cases}
\frac{1}{10 \pi^2 (403)^5 + 0.003690a}, & a \lesssim 1, \\
\frac{1}{(1/2)\pi^{1/2} a^{-1/2}}, & a \gtrsim 10^3,
\end{cases}
\]

but its values for \(0.1 \leq a \leq 10^3\) need to be computed numerically.

To determined the contributions of the static lattice contribution (Bragg diffraction) to neutrino Bremsstrahlung, we follow [20], who considered band structure effects. We begin with defining the dimensionless factor \(L_{\text{al}}\),

\[
L_{\text{al}} = \frac{1}{12Z_{\text{eff}}} \sum_{\mathbf{K} \neq 0} \frac{1 - y_K^2}{y_K^2} \left| F(K) \right|^2 \langle I(y, t_V) e^{-2W(y^2 \tilde{a}, t_p)} \rangle,
\]
which translates to a lower limit for $Z_{\text{eff}} \geq Z_{\text{eff,min}}^{(n)}$. The values of $Z_{\text{eff,min}}^{(n)}$ for $n = 1$ through $n = 5$ are shown in Table IV.

Therefore, since $Z_{\text{eff}} = Z$ in a lattice of nuclei immersed in an electron gas, $L_{\text{el}}$ is guaranteed to have a handful of terms. However, as we have seen in Section II C, the electron density will drop drastically with increasing baryon number density in the mixed phase region if $\chi \gtrsim 0.5$ so that $Z_{\text{eff}}$ drops correspondingly (see Fig. 9 where the first few $Z_{\text{eff,min}}^{(n)}$ are shown).

As will be shown in Section IV, for low temperatures of $T \lesssim 10^8 K$ and a quark volume fraction $\chi \gtrsim 0.5$ the summation consist only of a few terms, and the contribution of the static lattice oscillates vividly as a function of $\chi$ (see Figs. 11 and 12.)

C. Thermal conductivity

To calculate the thermal conductivity of quark-hybrid matter, we closely follow the formalism outlined in [21]. In general, the thermal conductivity of degenerate electrons is expressed in terms of an effective collision frequency $\nu_{\text{e}}$ [43],

$$\kappa = \frac{\pi k_B^2 T n_e}{3 m_e^2 \nu_{\text{e}}} ,$$

which, in turn, can be expressed in terms of dimensionless Coulomb logarithms $\Lambda_{\text{e}}$ [44],

$$\nu_{\text{e}} = \frac{4 \pi Z^2 e^4 n_b}{p_F v_F} \Lambda_{\text{e}} ,$$

where $n_b$ is the number density of rare phase blobs in the mixed phase, and $p_F$ and $v_F$ are the Fermi momentum and Fermi velocity of relativistic electrons. For a solid phase, the Coulomb logarithms are calculated variationally in Born approximation [21, 43],

$$\Lambda_{\text{e, solid}} = \int_{y_0}^{1} dy S_{\text{e}}(y) \left( F(y)^2/y(\epsilon(y))^2 \right) \delta S_{\text{e}}(y) .$$

Here, $y = q/(2k_F)$ and $S_{\text{e}}(y)$ are effective structure factors used to calculate the electric conductivity $\sigma$ [21].

Instead of using the asymptotic expressions and fitted formulas for $\Lambda_{\text{e}}$ provided in [21], which cover $10^{-3} < t_p < 10$ and $0 < \tilde{\alpha} \tilde{y}^2 < 0.15$ ($\tilde{\alpha}$ is given by Eq. (32)), here we fully calculate their values and derive their asymptotic behaviors. This covers a wider range of $t_p$ and $\tilde{\alpha} \tilde{y}^2$ values. For this purpose, we rewrite the relevant integrals given in [21, 42] in a form which is similar to $S_{\text{eff}}$ in Section III B, i.e.,

$$S_{\sigma}(y^2 \tilde{\alpha}_p, t_p) = \int_{0}^{\infty} \frac{d\xi}{\cosh^2 \pi \xi} \left( e^{y^2 \tilde{\alpha}_p \psi(\xi, t_p)} - 1 \right) \times e^{-2W(y^2 \tilde{\alpha}_p, t_p)} ,$$

$$\delta S_{\sigma}(y^2 \tilde{\alpha}_p, t_p) = \int_{0}^{\infty} \frac{d\xi}{\cosh^4 \pi \xi} \times e^{-y^2 \tilde{\alpha}_p \psi(\xi, t_p)} ,$$

where $\psi(\xi, t_p)$ denotes the phonon sum function already defined in Eq. (39). Since Bragg diffraction does not contribute to the thermal conductivity, there is no counterpart to $L_{\text{el}}$.

Similar to Section III B, asymptotic expressions for $\psi(\xi, t_p)$ may be used to derive the high and low temperature limits for $S_{\sigma}$ and $\delta S_{\sigma}$. One then obtains

$$S_{\sigma}(x, t_p) \overset{t_p \ll 1}{\rightarrow} G_{\sigma}(x, t_p \psi(0, t_p)) e^{-2W(x, t_p)} ,$$

$$\delta S_{\sigma}(x, t_p) \overset{t_p \gg 1}{\rightarrow} H_{\sigma}(x, t_p \psi(0, t_p)) e^{-2W(x, t_p)} ,$$

$$G_{\sigma}(a) \equiv \int_{0}^{\infty} \frac{d\xi}{\cosh^2 \pi \xi} \left( e^{a \psi(\xi)} - 1 \right) ,$$

$$G_{\delta \sigma}(a) \equiv \int_{0}^{\infty} \frac{d\xi}{\cosh^4 \pi \xi} e^{a \psi(\xi)} ,$$

$$H_{\sigma}(a) \equiv \int_{0}^{\infty} \frac{d\xi}{\cosh^2 \pi \xi} e^{-a \psi(\xi)} ,$$

$$H_{\delta \sigma}(a) \equiv \int_{0}^{\infty} \frac{d\xi}{\cosh^4 \pi \xi} e^{-a \psi(\xi)} .$$

The quantities $\psi(t_p)$ is defined in Section III B. The asymptotic limits of Eqs. (58) through (61) are given by

$$G_{\sigma}(a) \sim \begin{cases} e^a, & a \gtrsim 10^2, \\ \frac{2}{\pi} a, & a \lesssim 0.1, \end{cases},$$

$$G_{\delta \sigma}(a) \sim \begin{cases} e^a, & a \gtrsim 10^3, \\ \frac{a}{\pi^2}, & a \lesssim 10^{-2}, \end{cases},$$

$$H_{\sigma}(a) \sim \begin{cases} \frac{1}{4} \pi^{3/2} a^{-1/2}, & a \gtrsim 10^2, \\ 1 - \frac{5}{4}, & a \lesssim 0.1, \end{cases},$$

$$H_{\delta \sigma}(a) \sim \begin{cases} \frac{1}{2} \pi^{3/2} a^{-1/2}, & a \gtrsim 10^3, \\ 2a, & a \lesssim 10^{-2}. \end{cases}$$

### Table IV. Lower bound values $Z_{\text{eff,min}}^{(n)}$

| $Z_{\text{eff,min}}^{(1)}$ | $Z_{\text{eff,min}}^{(2)}$ | $Z_{\text{eff,min}}^{(3)}$ | $Z_{\text{eff,min}}^{(4)}$ | $Z_{\text{eff,min}}^{(5)}$ |
|-------------------------|-------------------------|-------------------------|-------------------------|-------------------------|
| $\sqrt{2}/3$ | $4\pi/3$ | $\sqrt{6}\pi$ | $8\sqrt{2}/3$ | $5\sqrt{10}\pi/3$ |
For $a$ values outside the ranges listed above the values of $H$ and $G$ were calculated numerically. Asymptotic approximations for $S_\kappa$ were used for $t_p \lesssim 10^{-2}$ and $t_p \gtrsim 1$. For $t_p$ values outside of these intervals the expression for $S_\kappa$ was computed numerically. The asymptotic approximations for $\delta S_\kappa$ are valid, and have been used, for $t_p$ values in the intervals $t_p \lesssim 10^{-2}$ and $t_p \gtrsim 10$.

D. Specific heat

The calculation of the specific heat is much simpler than the calculation of the neutrino emissivities and of the thermal conductivity, since the specific heat does not involve scattering processes. In terms of the phonon sum we use $\Gamma_m$ instead of the outdated value $\Gamma_m = 172$ (as in Sections III B and III C) instead of the outdated value $\Gamma_m = 150$ [45].

IV. RESULTS AND DISCUSSION

A. Contribution to the specific heat

In this paper, we have calculated the specific heat stemming from rare phase blobs immersed in hadronic matter for four different parameter sets (see Table III) and three different values ($\eta = 0.5, 1, 2$) for the surface tension of rare phase blobs. It is intriguing to compare these results with the heat capacities of the hadronic and quark matter phases, weighted by their volume fractions. For this purpose we compute the specific heat of a Fermi gas of leptons and baryons from

$$c_V^\ell = \frac{k^3_B}{4\pi^4} T \sqrt{m^2_\ell + k_F^2},$$

$$c_V^b = \frac{k^3_B}{4\pi^4} T \sum_B m^2_B k_{F,B},$$

where $m^2_B$ is effective in-medium mass of baryons (see Section II). The specific heat of a quark gas is given by [46]

$$c_V = 0.6 \times 10^{20} \left( \frac{n}{\rho_0} \right)^{2/3} T^3 \text{ ergs cm}^{-3} \text{ K}^{-1}.$$  (68)

The total specific heat of a mixture of quarks and hadrons follows from $c_V = (1 - \chi)c_V^\ell + \chi c_V^q$ where $c_V^\ell = c_V^\ell + c_V^b \chi$ and $c_V^q = c_V^q + c_V^b \chi$. Figure 10 compares the different contributions to the specific heat with one another. As can be seen, the contribution of the rare-phase blobs to the specific heat (colored lines in Fig. 10) is typically several orders of magnitude smaller than the specific heat of a standard (no geometrical structures) quark-hadron gas.

![Graph showing specific heat contributions](image-url)

FIG. 10. (Color online) Specific heat, $c_V$, of mixed quark-hadron phase as a function of quark volume fraction, $\chi$, computed for different surface tensions, $\eta$, and temperatures, $T$. The underlying equation of state is HV1. The panel on the left hand side shows the contributions of the rare-phase blobs to the specific heat. The curves in the panel on the right hand side show the specific heat computed for a standard (no geometrical structures) quark-hadron gas.

B. Neutrino Bremsstrahlung emissivity

The neutrino Bremsstrahlung emissivities emerging from electron-phonon scattering and electron-lattice

$$\sigma_T \propto T^3 (\sqrt{1 - \chi} + \chi),$$

and

$$\sigma_T \propto T (\sqrt{1 - \chi} + \chi).$$

These results are in agreement with previous calculations.

C. Contributions to the total specific heat

The specific heat of a standard quark hadron phase is given by

$$c_V^{\text{standard}} = \frac{k^3_B}{4\pi^4} T \left( \frac{1 - \chi}{\chi} \right) \left( \frac{1}{\sqrt{1 - \chi}} + \chi \right),$$

where $m^2_{\ell,b}$ are effective masses of leptons and baryons in medium.

D. Neutrino Bremsstrahlung emissivity

The neutrino Bremsstrahlung emissivities emerging from electron-phonon scattering and electron-lattice

$$\sigma_T \propto T^3 (\sqrt{1 - \chi} + \chi),$$

and

$$\sigma_T \propto T (\sqrt{1 - \chi} + \chi).$$

These results are in agreement with previous calculations.

E. Contributions to the total specific heat

The specific heat of a standard quark hadron phase is given by

$$c_V^{\text{standard}} = \frac{k^3_B}{4\pi^4} T \left( \frac{1 - \chi}{\chi} \right) \left( \frac{1}{\sqrt{1 - \chi}} + \chi \right),$$

where $m^2_{\ell,b}$ are effective masses of leptons and baryons in medium.

F. Neutrino Bremsstrahlung emissivity

The neutrino Bremsstrahlung emissivities emerging from electron-phonon scattering and electron-lattice

$$\sigma_T \propto T^3 (\sqrt{1 - \chi} + \chi),$$

and

$$\sigma_T \propto T (\sqrt{1 - \chi} + \chi).$$

These results are in agreement with previous calculations.
(Bragg diffraction) scattering have been computed from Eqs. (33) for the four parameter sets of Table III. The surface tension of rare phase blobs in Eq. (24) has been varied again from \( \eta = 0.5, 1, \text{to} 2 \). Figures 11 and 12 show the contributions of the rare phase blobs to the neutrino Bremsstrahlung emissivity as a function of the quark volume fraction. A range of representative temperatures, from \( T = 10^7 \text{K} \) to \( 10^{11} \text{K} \) has been chosen. For comparison, we show the contributions to the neutrino emissivity which comes from the modified Urca process in hadronic matter, \( \epsilon_{\nu,H,MU} \), and in quark matter, \( \epsilon_{\nu,Q,MU} \) [46]. Finally, we also show in these figures the emissivities which correspond to nucleon Bremsstrahlung, \( \epsilon_{\nu,H,BR} \) and quark Bremsstrahlung, \( \epsilon_{\nu,Q,BR} \) [9, 46]. Their total contribution in quark-hybrid star matter is obtained, for a given quark volume fraction \( \chi \), from \( \epsilon_{\nu} = \chi \epsilon_{Q} + (1 - \chi) \epsilon_{H} \). As can be seen from Figs. 11 and 12, the neutrino emissivity from electron-blob Bremsstrahlung becomes comparable to the emissivities of the modified Urca process (and other Bremsstrahlung processes) for temperatures \( T \lesssim 10^9 \text{K} \).

The Bremsstrahlung emissivities oscillate rapidly with \( \chi \) for \( T \lesssim 10^9 \) and \( \chi \gtrsim 0.5 \). This is due to Bragg diffraction, given by the sum in the expression for \( L_{sl} \) (see Eq. (51)). As mentioned in Section III B, the sum of \( L_{sl} \) consists only of a few terms if \( \chi \gtrsim 0.5 \). The oscillations are essentially due to the oscillating values of the individual terms in Eq. (51). The oscillations are smoothed out when the number of terms is large.

It also follows from Figs. 11 and 12 that the neutrino emissivity of rare phase blob Bremsstrahlung, at low temperatures but greater quark volume fractions (\( \chi \gtrsim 0.5 \)), becomes sensitive to the choice of \( \eta \). This feature, however, does not lead to large uncertainties in the total neutrino emissivity, since the neutrino emissivities for this temperature-density regime are dominated by the modified Urca process and nucleon-nucleon and quark-quark Bremsstrahlung processes.
in standard quark-hadron gas without blobs is given by

$$\kappa = \left( \frac{\chi}{\kappa_Q} + \frac{1 - \chi}{\kappa_H} \right)^{-1}, \quad (69)$$

Besides scattering between electron and rare phase blobs calculated in §III C, the geometric pattern will also alter the total thermal conductivity. The two contributions $\kappa_H$ and $\kappa_Q$ from standard quark-hadron gas can be combined using an expression for the total effective thermal conductivity of spheres immersed in continuous matter of a different thermal conductivity [49]. In our case the bulk thermal conductivity of two phases can be written as

$$\kappa_{\text{eff}} = \kappa_1 \left( 1 - \frac{3\chi}{(2\kappa_1 + \kappa_2)/(\kappa_1 - \kappa_2) + \chi} \right), \quad (70)$$

where $\kappa_1$ and $\kappa_2$ are the thermal conductivities of the dominant and the rare phase, respectively.

The small jumps of thermal conductivities from electron-blob scattering (color lines in Figs. 13 through 16) are due to discontinuities of rare phase blob mass $m_b$ (See Fig. 7). The jumps of thermal conductivities contributed by embedding of rare phase blobs (thin black lines in Figs. 13 through 16) are due to unequal thermal conductivities of the two phases $\kappa_1 \neq \kappa_2$ at $\chi = 0.5$.

As can be seen from Figs. 13 through 16, the total thermal conductivity $\kappa = (\kappa_{\text{eff}} + \kappa_{\text{blob}})^{-1}$ is dominated by electron-blob scattering at $T \lesssim 10^{10} K$. This is particularly the case for quark volume fractions close to $\chi = 0$ or $\chi = 1$ where the electron thermal conductivity from blob scattering can be as much as three (for $\chi < 0.5$) to six orders of magnitude ($\chi > 0.5$) smaller than the contribution from the mixed quark-hadron phase. Physically, this causes a blocking of the thermal flow through a mixed quark-hadron phase region, which could manifest itself in the thermal evolution of quark-hybrid stars.

As mentioned in Section II C, the blob volume density $n_b \to 0$ as $\chi \to 0$ or $\chi \to 1$. Since the Coulomb logarithm $\Lambda_\kappa$ is finite for these limits but the coefficient $\kappa_{\text{eff}}$ is divergent, the thermal conductivity stemming from rare phase blob scattering will diverge on both ends of the quark-hadron phase, leading to a vanishing total thermal conductivities there. Since this occurs only very near the edges of the quark-hadron boundary ($\chi \lesssim 10^{-2}$) this
feature can not be seen in Fig. 13. The small jumps in $\kappa$ near the edges of the quark-hadron phase for $T = 10^9$ K and $10^{10}$ K (see Figs. 14 and 16) are due to melting.

V. SUMMARY AND CONCLUSIONS

Because of the competition between the Coulomb and the surface energies associated with the positively charged regions of nuclear matter and negatively charged regions of quark matter, the mixed phase may develop geometrical structures (e.g., blobs, rods, slabs), similarly to what is expected of the sub-nuclear liquid-gas phase transition. In this paper we explore the consequences of a Coulomb lattice made of rare phase blobs for the thermal and transport properties of neutron stars. The total specific heat, $c_V$, thermal conductivity, $\kappa$, and electron-blob Bremsstrahlung neutrino emissivities, $\epsilon_{\nu, BR}$, are calculated and compared with those of standard neutron star matter. To carry out this project, we have adopted, and expanded on, methods of earlier works on the transport properties of neutron stars [7, 25]. The sizes of, and spacings between, rare phase blobs are calculated using the Wigner-Seitz approximation [7]. The equations of state used in this study are computed for a standard non-linear nuclear Lagrangian, and the associated equations of motion for the baryon and meson fields are solved in the relativistic mean-field approximation. Quark matter has been modeled in the framework of the MIT bag model. Four different parameter sets (HV1, HV2, G300I, G300II) have been used to model the composition of neutron star matter containing a mixed phase of quarks and hadrons (quark-hybrid matter).

The results discussed in Section IV show that the contribution of rare phase blobs in the mixed phase to the specific heat is negligible compared to the specific heat of a quark-hadron gas. This is very different for the transport properties. For low temperature $T \lesssim 10^8$ K the neutrino emissivity from electron-blob Bremsstrahlung scattering is at least as important as the total contribution from other Bremsstrahlung processes (such as nucleon-nucleon and quark-quark Bremsstrahlung) and modified nucleon and quark Urca processes (see Figs. 11 and 12). It is also worth noting that the scattering of degenerate electrons off rare phase blobs in the mixed phase region lowers the thermal conductivity by several orders of magnitude compared to a quark-hadron phase without geometric patterns (see Figs. 13 through 16). This may lead to significant changes in the thermal evolution of the neutron stars containing solid quark-hadron cores, which will be part of a future study. Another very interesting issue concerns the impact of more complex geometrical structures (rods and slabs) on the thermal conductivity and on neutrino transport. The presence of such structures...
may reduce the neutrino emissivities because of changes in the dimension of the reciprocal lattice and the Debye-Waller factor [20].

In summary, our study has shown that the presence of rare phase blobs in dense neutron star matter may have very important consequences for the total neutrino emissivity and thermal conductivity of such matter. The implications of this for the thermal evolution of neutron stars need to be explored in future studies. To accomplish this we intend on performing two dimensional cooling simulations, in which rotation and a dynamic composition might be accounted for [50, 51]. In this connection we refer to the recent study of Noda et al. [52], who suggested that the rapid cooling of the neutron star in Cassiopeia A can be explained by the existence of a mixed quark-hadron phase in the center of this object.
