Abstract. Successful treatment of veterinary infectious diseases in the context of widespread use of antibiotic therapy depends on the effectiveness of the drugs used to contain or destroy the etiological agent. It is generally accepted that the resistance of microorganisms to antimicrobial agents is variable, including due to the horizontal movement of resistance with the help of mobile genetic elements. Antimicrobial susceptibility pattern analysis is an important component of the diagnosis and treatment of veterinary diseases. The article describes a study that includes isolation and identification of microorganisms from samples taken from pathological material of pigs and the analysis of sensitivity to eleven antimicrobial drugs by the disk-diffusion method.

1 Introduction

Successful treatment of veterinary infectious diseases in the context of widespread use of antibiotic therapy depends on the effectiveness of the drugs used to contain or destroy the etiological agent [1-4]. It is generally accepted that the resistance of microorganisms to antimicrobial agents is variable, including due to the horizontal movement of resistance with the help of mobile genetic elements [5-7].

In order to monitor the sensitivity of microbiota to antimicrobial substances, samples of pathological material from pig corpses from pig breeding complexes in Russia were taken from March to May 2021. The species identification of the isolated microorganisms was determined and the parameters of sensitivity to antimicrobial substances, which are widely presented on the market in the composition of medicines for veterinary use, were determined.

2 Methods

In laboratory conditions, 14 washes were analyzed from pathological material from pig corpses. Washes were delivered within 24 hours in a heat-insulating box equipped with

* Corresponding author: matrenov.is@yandex.ru
cold accumulators at a temperature not exceeding 8 °C, which was confirmed by the readings of an electronic thermometer with the function of periodically recording readings. The Cary-Blair medium was used as a transport medium. The studies were carried out in accordance with the CLSI recommendations [8] by the disk-diffusion method. A set of antibiotics of the following composition was used: amoxicillin (AMC), amoxicillin + clavulanic acid (AMK), azitronite (AZT), doxycycline (DXC), colistin (COL), levofloxacin (LVC), tiamulin (TML), tilmicosin (TMS), florfenicol (FLF), ceftiofur (CFF), enrofloxacin (EFC). The washing sampling sites were determined by clinical signs similar to the manifestations of pig pleuropneumonia and hemophilosis, as well as the pathological picture of the autopsy objects. The isolated isolates were identified using API biochemical tests developed and manufactured by BioMérieux. The API test results were interpreted using the APIWeb service. The experimental design included 6 parallel measurements of the sensitivity of one strain to one antimicrobial substance (n = 6). The results were statistically processed according to standard procedures using Microsoft Excel 2016 (Microsoft Corp. USA) and the statistical data analysis package StatPlus 2009 Professional 5.8.4 for Windows (StatSoftInc., USA) [9]. The experiment used a control strain of the museum culture E. coli ATCC 25922.

3 Results

The study results are shown in Table 1.

4 Discussion

Identification was considered valid if the service assigned the analyzed results a score of "Good identification" and "Excellent identification". The standard deviation of the parallel growth inhibition values did not exceed 2.0. Interpretation of the obtained sizes of the growth inhibition zones is difficult: the standard [8] does not include the full range of the studied materials. It shall also be noted that standards [10] and [11] similarly do not contain information for distribution of all obtained isolates into groups (sensitive, moderately sensitive, resistant) to a particular substance used in the experiment with antimicrobial properties. To interpret the results that are not unambiguously described in the current standards for antimicrobial susceptibility (MUK RF, CLSI, EUCAST), it is possible to use the explanations to the standard [11] described in appendix [12].

The data obtained by us were interpreted according to the fact of the complete absence of the growth inhibition zone around the disc with the antimicrobial drug. 18 out of 25 isolated strains showed complete resistance (no zone of inhibition) to at least one of the antimicrobial substances. Where, strains 3, 9, 11, 13, 15, 16, 19, 21, 24, 25 are multi-resistant (resistance to three or more antimicrobial substances of different classes), which is 40 % of the total number of isolates studied.

4. Conclusion

As a result of the work carried out, we have identified multi-resistant strains of microorganisms. There are no cases of complete resistance to all tested antimicrobial substances. The highest efficiency in relation to the studied cultures was shown by
enrofloxacin, ceftiofur, levofloxacin (1 strain with full resistance out of 25 studied), azitronite (2 out of 25). No strains have been identified that are fully resistant to florfenicol.
