ABSTRACT

We present our new deep optical imaging and long-slit spectroscopy for Arp 220, the archetypical ultra luminous infrared galaxy in the local universe. Our sensitive Hα imaging has newly revealed large-scale Hα absorption, i.e., post-starburst regions in this merger. One is found in the eastern superbubble and the other is in the two tidal tails that are clearly revealed in our deep optical imaging. The size of the Hα absorption region in the eastern bubble is 5 kpc × 7.5 kpc, and the observed Hα equivalent widths are ∼2 Å ± 0.2 Å. The sizes of the northern and southern Hα-absorption tidal tails are ∼5 kpc × 10 kpc and ∼6 kpc × 20 kpc, respectively. The observed Hα equivalent widths range from 4 Å to 7 Å. In order to explain the presence of the two post-starburst tails, we suggest a possible multiple-merger scenario for Arp 220 in which two post-starburst disk-like structures merged into one, causing the two tails. This favors Arp 220 as a multiple merging system composed of four or more galaxies arising from a compact group of galaxies. Taking our new results into account, we discuss a star formation history in the last 1 Gyr in Arp 220.

Key words: galaxies: individual (Arp 220) – galaxies: interactions – galaxies: starburst

1. INTRODUCTION

Ultra luminous infrared galaxies (ULIRGs) whose infrared (8–1000 μm) luminosity exceeds 10^{12} L⊙ are the sites where extraordinarily active star formation occurs in their central regions, triggered by galaxy mergers (Sanders et al. 1988). Since such galaxies have also been found as massive, dusty galaxies at high redshift, providing substantial star formation in the early universe (Le Floc’h et al. 2005), it is important to unambiguously understand their physical origins.

Originally, Sanders et al. (1988) proposed that ULIRGs come from a merger between two gas-rich galaxies. On one hand, multiple-merger scenarios have also been proposed for the formation of ULIRGs based on their morphological and dynamic properties (Taniguchi & Shioya 1998; Borne et al. 2000; Haan et al. 2011). Unlike well-defined, ongoing merging systems such as the Antennae (NGC 4038 + NGC 4039), most ULIRGs appear to have complicated morphological properties of so-called advanced mergers (e.g., Sanders & Mirabel 1996).

The following questions have not yet been settled unambiguously for the origin of ULIRGs: (1) How many galaxies were merged into one? (2) Which types of galaxies were merged into one? (3) What were their orbital parameters? Since the merging of galaxies can smear out morphological properties of the original galaxies that took part in the merger, it is generally difficult to give firm answers to the preceding questions (e.g., Weil & Hernquist 1996; Bournaud et al. 2007).

It is worthwhile noting that a major merger between two galaxies may be a site of multiple mergers because any galaxy has its satellite galaxies (Wang & White 2012 and references therein). For example, let us imagine the case of the merger between our Galaxy and M 31. Since both galaxies have two significant satellite galaxies (LMC and SMC for our Galaxy and M32 and NGC 205 for M31), this major merger includes six galaxies. Since a minor merger also gives dynamic disturbance to its host disk galaxy (e.g., Mihos & Hernquist 1996; Taniguchi et al. 1996; Bournaud et al. 2007; Villabos & Helmi 2008), it seems to have an unambiguous discrimination between a major merger between two galaxies and a multiple merger. It is also worthwhile noting that numeric simulations of multiple mergers can make an Arp 220-like morphology during the course of mergers among six galaxies (Weil & Hernquist 1996). A one-sided long tidal tail structure (e.g., Mrk 273) can also be generated by a multiple-merger model (Bekki 2001).

Among the ULIRGs in the local universe, Arp 220 is the archetypical advanced merger (Sanders et al. 1988; Joseph & Wright 1985). Arp 220 shows at least two starburst events: one is the central super star clusters (i.e., the ongoing starburst; Shaya et al. 1994; Taniguchi et al. 1998), and the other is the figure “8” shaped structure of ionized gas driven by a superwind (Heckman et al. 1987, 1990, 1996). It is also suggested that there is a hidden starburst core in the central region of Arp 220 that is seriously obscured, AV ≈ 30–50 mag (e.g., Anantharamaiah et al. 2000; Shioya et al. 2001). Indeed, multi-phase star formation events in Arp 220 and other ULIRGs have been identified in more recent imaging and spectroscopic investigations (e.g., Wilson et al. 2006; Rodríguez Zaurín et al. 2008, 2009; Soto & Martin 2010). Accordingly, Arp 220 appears to have experienced a long history of episodic starbursts during the course of merging within the last ∼1 Gyr.

* Based on data collected at the Subaru Telescope, which is operated by the National Astronomical Observatory of Japan.
This complicated star formation history in Arp 220 may come from a multiple merger including more than two galaxies (e.g., Taniguchi & Shioya 1998; Borne et al. 2000). It is generally difficult to explore the history of such multiple mergers in an advanced merger phase. However, since Arp 220 shows the ongoing and past starburst events noted above together with a faint pair of tidal tails, it is worthwhile investigating its star formation history in greater detail. For this purpose, we have carried out deep Hz imaging using the Subaru Telescope and a long-slit spectroscopic observation with the Keck II Telescope. Based on our new observations, we discuss a possible scenario for the star formation history in Arp 220 and re-visit a multiple-merger scenario.

We use the distance of 77.6 Mpc toward Arp 220 that is estimated with both the systemic velocity of 5434 km s\(^{-1}\) (de Vaucouleurs et al. 1991) and a Hubble constant of \(H_0 = 70\) km s\(^{-1}\) Mpc\(^{-1}\). At this distance, 1′ corresponds to 376 pc.

2. OBSERVATIONS

2.1. Optical Imaging

In order to understand the whole star formation history in Arp 220, one efficient method is to reveal post-starburst regions (their characteristic ages are \(\sim 0.2–1\) Gyr) as well as the ongoing active star-forming regions (their characteristic ages are \(< 10\) Myr). For this purpose, we obtained deep Hz on-band and off-band frames using the Faint Object Camera And Spectrograph (FOCAS) on the Subaru Telescope on 2002 September 15 (UT). Total integration times for the on and off bands were 8400 s and 2400 s, respectively. The center wavelengths and bandwidths were 6709 Å and 85 Å and 6588 Å and 73 Å for the on and off bands, respectively. The on-band frames include stellar continuum emission and H\(\alpha\) off bands, respectively. The sizes of the northern and southern H\(\alpha\) absorption regions in Arp 220 are \(\sim 20\) kpc and \(\sim 20\) kpc, respectively. Since the eastern H\(\alpha\) absorption region and the two tidal tails have the same color indices (Section 3), this continuum correction is reasonable. The spatial resolution of FOCAS images was 0′.7.

Deep R-band frames of Arp 220 were also obtained by the Subaru Prime Focus Camera (Suprime-Cam) on 2004 February 18 (UT). Bias subtraction, flat-fielding, and sky subtraction were performed. The total integration time was 4200 s, and the spatial resolution was 1′/0. This R-band image was used to find faint tidal features around Arp 220 (see also Koda et al. 2009).

2.2. Optical Spectroscopy

A new optical spectrum was obtained by the Low Resolution Imaging Spectrometer (LRIS; Oke et al. 1995) with the Keck II Telescope on 1997 April 16 (UT). A 900 s exposure was taken with the 600 line mm\(^{-1}\) grating, with a central wavelength setting of 6024 Å. The grating is blazed at 5000 Å and the dispersion is 1.28 Å pixel\(^{-1}\). The observed wavelength range and the spectral resolution were 4670–7210 Å and 6.9 Å, respectively.

The 1′ slit with a length of 66′′ was oriented at the position angle of 130° to observe simultaneously both the nucleus of Arp 220 and its visual companion D (seen at SE of Arp 220). The spectrum was reduced using IRAF in the standard manner, i.e., wavelength calibration, flat-fielding, and flux calibration (see Ohyama et al. 1999 for detail).

3. RESULTS

3.1. Imaging Data

In post-starburst regions, massive OB stars have already ceased; thus, intermediate-mass stars such as A-type stars dominate the population. Such regions are probed by strong hydrogen Balmer absorption lines (e.g., Taniguchi et al. 1996).

Figure 1 shows the continuum-subtracted, smoothed H\(\alpha\)+ [N\(\text{II}\)] \(\lambda\lambda 6548, 6583\) image and the H\(\alpha\) equivalent width maps obtained by FOCAS, respectively. We detect strong H\(\alpha\) emission from the central region of Arp 220 and shell-like structures in both the SE and NW directions, as already reported in the literature (Heckman et al. 1987, 1990, 1996). The strong H\(\alpha\) emission from the central region is considered to be attributed to the ongoing starburst activity there. On the other hand, the shell-like structures are due to the recent-past supernova, which is a galactic-scale outflow caused by many supernovae.

On closer inspection, we find three H\(\alpha\) absorption regions. One H\(\alpha\) absorption region is detected about 20′ east from the center, inside the eastern H\(\alpha\) bubble. The observed equivalent width of H\(\alpha\) in the center 3′′ × 3′′ is 2.3 Å ± 0.15 Å (1\(\sigma\)). The size of this region is approximately 5 kpc × 7.5 kpc. The other two spectacular H\(\alpha\) absorption regions appear to be associated with the two optically faint tidal tails found in our deep R-band image (see also Figure 2). The observed equivalent width of H\(\alpha\) amounts to \(\sim 5\) ± 0.4 Å in total; \(\sim 4\) ± 1.1 Å at the continuum flux peak and \(\sim 7\) ± 1.7 Å at the outer side of the tails (Figure 3).

The sizes of the northern and southern H\(\alpha\) absorption regions are \(\sim 5\) kpc × 10 kpc and \(\sim 6\) kpc × 20 kpc, respectively. Since these three regions show the H\(\alpha\) absorption feature, A-type stars, or post-starburst populations, are dominant in the optical continuum without H\(\alpha\) emission sources such as OB stars.

Figure 4 displays Arp 220 color index maps obtained from SDSS images (Abazajian et al. 2009). We find that the three H\(\alpha\) absorption regions have almost the same color indices. Furthermore, their color indices within several kpc, except for the nuclear region, are similar to those of the H\(\alpha\) absorption regions. These facts suggest that the dominant stellar populations at these regions are the same, i.e., post-starburst, which is consistent with the results of Rodríguez Zaurín et al. (2008) and Soto & Martin (2010).

Finally, we comment on the alternative interpretation that H\(\alpha\) absorption in the two tidal tails could be caused by the high extinction found in a number of ULIRGs (e.g., Rodríguez Zaurín et al. 2009). If the extinction is high enough to hide ongoing massive star formation, then the observed optical light might be dominated by intermediate-type stars, resulting in strong H\(\alpha\) absorption with little emission line. Although such situations may occur in the central parts of ULIRGs including Arp 220 (Shioya et al. 2001), it seems unlikely that such very dusty starbursts occurred in the entire regions of both the eastern bubble and the two tidal tails. Therefore, we consider that the post-starburst interpretation is a more robust idea for the observed H\(\alpha\) absorption regions in Arp 220.
Figure 1. Left panel: continuum-subtracted, smoothed Hα+[N II] λλ6548, 6583 intensity map. Right panel: Hα equivalent width map of Arp 220 obtained by FOCAS. The color ranges are from $-1 \times 10^{-18}$ to $5 \times 10^{-18}$ erg cm$^{-2}$ s$^{-1}$ (0.20 arcsec)$^{-2}$ for the Hα+[N II] intensity map and from 10 to $-30$ Å (positive value means absorption) for the Hα equivalent width map. The contours are shown at 2, 6, and 10 Å in the Hα equivalent width in absorption. North is up and east is left. The slit position in the long-slit spectroscopic observation is shown with the diagonal green box. Two red rectangles represent the positions where continuum surface brightness and equivalent widths are shown in Figure 3. The green bar in each panel at the lower right corresponds to 10 kpc.

(A color version of this figure is available in the online journal.)

Figure 2. R-band image of Arp 220 obtained by Suprime-Cam (right panel) with the post-starburst regions shown by red contours. For comparison, the HST/ACS image of Arp 220 is also shown in the left panel (http://hubblesite.org/gallery/album/pr2008016aq/). North is up and east is left. The post-starburst regions are shown by red-color contours. The green bar corresponds to 10 kpc.

(A color version of this figure is available in the online journal.)
Figure 3. Continuum surface brightness and Hα equivalent width profiles at (a) northern and (b) southern tails using FOCAS data. Solid lines represent continuum surface brightness in an arbitrary unit (−10 Å corresponds to no flux), while filled circles represent equivalent widths. The slit positions are shown in Figure 1. The aperture size in each data point is 2′′ × 8′′. Uncertainties in continuum surface brightness are almost the same at all positions, and only the rightmost one is shown.

3.2. Spectroscopic Data

The so-called Lick index (Worthey & Ottaviani 1997) provides a common method for calculating an equivalent width. We therefore calculated the Hβ Lick index as a function of slit position. Hα equivalent width was also calculated in the same way as the Lick index. Note that we adopt the following wavelength coverage: 6552.4−6564.6 Å for the on-Hα region, and 6505.9−6525.4 Å and 6603.7−6664.9 Å for the off-Hα region. We chose these ranges in order to avoid the effects from [N II] λλ6548, 6583 emission from the object, other absorption lines, and sky emission.

Figure 5 represents continuum flux density and equivalent width profiles along the slit position displayed in Figure 1. The Hα equivalent width at the southern part of the eastern bubble is ∼1.5 Å, i.e., Hα absorption, which is consistent with the FOCAS equivalent width map (Figure 3). The Hβ equivalent width is more sensitive to the post-starburst population than that of Hα, because the flux of the Hβ emission line is generally about three times smaller than the Hα flux (e.g., Osterbrock & Ferland 2006). The observed Hβ Lick index of the eastern Hα absorption region is 3−4 Å. Hβ absorption is detected not only around the eastern bubble, but also in the central region of Arp 220, ∼45′′ and ∼−5′′ from the center (Figure 5). This fact suggests that post-starburst populations spread to several kpc in diameter, which is consistent with the results of both Rodríguez Zaurín et al. (2008) and Soto & Martin (2010). Unfortunately, we cannot measure the Hβ equivalent width of the west Hα absorption tails because they were out of the field of view of LRIS.

4. DISCUSSION

4.1. A Multiple-merger Scenario

Based on its morphology, it is obvious that Arp 220 is now in an advanced phase of a galaxy merger (Sanders et al. 1988). For Arp 220, Taniguchi & Shioya (1998) discussed the possibility of multiple mergers. Their argument is based on these facts: that Arp 220 has two compact starburst regions and that a pair of nuclei (i.e., a pair of supermassive black holes) is necessary to initiate the so-called nuclear starburst in a merging system in either a minor or a major merger (Taniguchi & Wada 1996). This may be a plausible idea because the starburst is intrinsically different from ordinary star formation in galactic disks (Daddi et al. 2010). The presence of multiple (at least three) OH megamaser sources can be interpreted as evidence for major mergers of four galaxies in Arp 220 (Diamond et al. 1989). However, although further observations detected multiple components, they do not necessarily suggest multiple nuclei (Rovilos et al. 2003).

One interesting advantage of the multiple-merger model by Taniguchi & Shioya (1998) is that they predicted the presence of a pair of counter rotating dense molecular gas disks before the actual observational detection by Sakamoto et al. (1999). Arp 220 is a very gas rich system with ∼10^{10} M_☉, and half of the gas is associated with two apparent eastern and western nuclei (Scoville et al. 1997). It seems difficult to estimate orbital parameters of merging galaxies to explain all these observational results.

However, the post-starburst tidal tails revealed by our new observations presented here suggest a possible new idea on the merging history in Arp 220. For further consideration of multiple mergers, we discuss the origin of Arp 220.

Here, we focus on the origin of two post-starburst tidal tails. First, in antenna-like tidal tails, one tidal tail emanates from one colliding galaxy; thus, two well-developed tidal tails are formed (Toomre & Toomre 1972). Taking this into account, we can postulate that two post-starburst systems merged into one and then the observed two post-starburst tails were formed in Arp 220. The observed smooth distribution of Hα absorption features requires this scenario, although small-scale star formation activity could occur in gaseous tidal tails (Barnes & Hernquist 1992; Duc & Mirabel 1998).

It should be noted that the size of each post-starburst system must be as large as several kpc at least, corresponding to a typical scale of disk galaxies. Let us consider a probable star formation history in a major merger between two disk galaxies. During the course of such merger evolution, enhanced star formation events occurred, triggered by inward gas flow driven by non-axisymmetricities in the galaxy disks (e.g., Di Matteo et al. 2007). However, it should be noted that the starburst events are essentially confined in the nuclear region of each galaxy, i.e., within only a few kpc diameter area. Note that this is comparable to those of nuclear starburst regions in disk galaxies (e.g., Balzano 1983). In order to make a pair of very large-scale (∼10 kpc), post-starburst tidal tails observed in Arp 220, we need two large-scale (∼several kpc), post-starburst disk-like structures. Such a structure can be made in an advanced phase of a merger between two disk galaxies, i.e., a major merger remnant. We therefore strongly suggest that the observed two tidal tails in Arp 220 need a merger between two advanced (i.e., post-starburst) merger remnants. Namely, we need four disk galaxies to explain the observed post-starburst tidal tails in Arp 220. We therefore conclude that Arp 220 comes not from a...
Figure 4. (a) $u' - g'$, (b) $g' - r'$, (c) $r' - i'$, and (d) $i' - z'$ color index maps obtained from SDSS images. The color scales are from $-1$ to $3$ mag for the $u' - g'$ map and from $-1$ to $1$ mag for the other maps. North is up and east is left. The white bar in each panel at the lower right corresponds to $10$ kpc.

(A color version of this figure is available in the online journal.)

typical merger between two galaxies, but from a multiple merger including four galaxies at least.

We estimate the traveling time of stars in the tidal tails from the merger center to the present place of tails. Given both the velocity of tidally liberated stars as $100$ km s$^{-1}$ and the distance as $20$ kpc, the traveling time is calculated as $200$ Myr, which is consistent with the lifetime of the post-starburst phase (0.2–1 Gyr). Our scenario for the evolution of Arp 220 is summarized in Figure 6.

4.2. Star Formation History in Arp 220

Finally, we consider a possible unified picture for various star formation events in Arp 220. As shown in Figure 1, there are two more important starburst features in Arp 220: one is the central starburst and the other is the pair of superbubbles caused by the superwind activity (Heckman et al. 1987, 1990, 1996; Colina et al. 2004). The central starburst must have occurred very recently, $<10$ Myr ago, taking into account the lifetime of massive OB stars. On the other hand, since the dynamic timescale of the observed superbubble is estimated as a few tens Myr (e.g., Heckman et al. 1990), Arp 220 experienced another starburst a few tens Myr ago. These star formation events correspond to those found in Rodríguez Zaurín et al. (2008).
In summary, taking into account the two post-starburst tails, we propose a unified evolution model for Arp 220 as shown in Figure 7. These three starburst events could be driven by sequential multiple mergers in Arp 220.

5. CONCLUDING REMARKS

There are a significant number of compact groups of galaxies in the local universe (Hickson 1982a, 1982b), leading to multiple mergers. Such compact groups of galaxies are also present in rich groups and outskirt regions of a cluster of galaxies at intermediate redshift (Mendel et al. 2011). Moreover, a possible multiple merging system has also been found at $z > 1$ (Schawinski et al. 2011).

ULIRGs are considered to evolve to quasars and then giant early-type galaxies (elliptical or S0 galaxies). A large number of high-redshift analogs of ULIRGs, so-called submillimeter galaxies, have been discovered beyond $z \sim 1$ (e.g., Hughes et al. 1998; Barger et al. 1998; Amblard et al. 2011; Magdis et al. 2011). Although major mergers between only two galaxies have been often considered in terms of the hierarchical evolution of galaxies from high redshift to the present day, we will have to take the impact of multiple mergers into account in future consideration.

We thank the staff of the Subaru Telescope for their professional help in our observations. We also thank the Hubble Space Telescope (HST)/COSMOS team members because the deep R-band image of Arp 220 was taken during a break in our COSMOS observing runs on the Subaru Telescope; in particular, we thank Nick Scoville, Dave Sanders, Bahram Mobasher, Herve Aussel, and Peter Capak. We thank Dave Sanders and Kirsten Larson for useful discussion on the global optical color properties of Arp 220. Finally, we thank the referees for the useful comments and suggestions that improved this paper.
